The tropics contain the overwhelming majority of Earth’s biodiversity: their terrestrial, freshwater and marine ecosystems hold more than three-quarters of all species, including almost all shallow-water corals and over 90% of terrestrial birds. However, tropical ecosystems are also subject to pervasive and interacting stressors, such as deforestation, overfishing and climate change, and they are set within a socio-economic context that includes growing pressure from an increasingly globalized world, larger and more affluent tropical populations, and weak governance and response capacities. Concerted local, national and international actions are urgently required to prevent a collapse of tropical biodiversity.

The tropics hold a disproportionate amount of global biological diversity and are key to meeting the international community’s aims of socially just sustainable development and effective biodiversity conservation. Yet, tropical ecosystems are undergoing rapid environmental, socio-economic and demographic change, often driven by forces originating in extra-tropical developed countries. The scale of these changes is unprecedented, and decisions implemented in the coming decades will define the future sustainability of the tropics.

Guiding these decisions depends on understanding the diversity and vulnerability of the four major tropical ecosystems: the forests and mesic savannahs that cover most of the terrestrial tropics, the extensive freshwater systems that receive half of the world’s rainfall and the shallow-water coral reefs distributed along 150,000 km of coastline. Here we quantify and review the global importance of tropical biodiversity, evaluate the vulnerability of tropical ecosystems to proximate stressors and assess whether global and regional socio-economic changes will exacerbate or ameliorate biodiversity loss. We then examine the effectiveness of conservation approaches and highlight the scientific advances required to support a sustainable tropical future.

The global importance of tropical ecosystems

Over evolutionary time, the tropics have acted as both a source of and a refuge for extra-tropical terrestrial and marine species2,4; but just how diverse and irreplaceable are the tropics today? The increase in species richness from polar to tropical regions, known as the latitudinal diversity gradient, is found across a wide range of taxa and biomes. As a result of this gradient, tropical latitudes – which cover just 40% of the Earth’s surface – hold a startling proportion of the planet’s species: our assessment reveals that almost all shallow-water zooxanthellae corals, 91% of terrestrial birds, and over 75% of amphibians, terrestrial mammals, freshwater fish, ants, flowering plants and marine fish have ranges that intersect tropical latitudes (Fig. 2a). For birds, the importance of the tropics extends far beyond 23.5 degrees of latitude, given that almost half of all Nearctic species migrate to the Neotropics9 and over 2 billion individual passerines and near-passerines cross the Sahara each autumn9.

Moreover, a disproportionate number of species are endemic to the tropics. For example, there are more than six times as many endemic terrestrial bird species in the tropics as in temperate regions (Fig. 2a). Tropical zones are less important for marine mammals and birds, which peak in diversity at mid-latitudes10,11. Nonetheless, more than 55% of these species use the tropics (Fig. 2a).

Overall, 78% of species across the ten taxa that we assessed occurred within tropical latitudes, but incomplete taxonomic inventories mean that this is almost certainly an underestimate9. Between 15,000 and 19,000 new species are described annually10, and the majority of recently described terrestrial vertebrates11 or predicted discoveries of invertebrates12 are from the tropics. Even terrestrial mammals are still being discovered at a rate of about 25 species a year, with the highest numbers in the Neo- and Afro-tropics13. Shortfalls in species descriptions for other taxa are often far greater. For example, only 70,000 of an estimated 830,000 multicellular plants and animals have been named on coral reefs14, and although approximately 500 spider species are described each year, this is a tiny fraction of the estimated 150,000 undescribed tropical species15.

Tropical taxonomic shortfalls are further compounded by a suite of systematic sampling biases. These include undersampling when compared with temperate regions15, the spatial aggregation of sampling effort around coastal areas17, roads, rivers, urban settlements and high-profile research stations18, biases in favour of dry-season sampling when many invertebrate taxa are least abundant19, and the paucity of samples from ecosystems that are harder to access, such as mesophotic and rariphotic reefs20. The biological diversity of the tropics is...

Fig. 1  The tropical biosphere. a, Tropical terrestrial and marine biomes. The tropical terrestrial biome (green) was defined as all tropical mesic ecoregions. These ecoregions span 82% of the 50 million km² of land between 23.5° N and 23.5° S, but extend into the subtropics in some areas. The tropical marine biome was defined by the 1988-2018 mean minimum monthly 18°C sea-surface isotherm. This isotherm bounds the latitudinal extent of shallow-water coral-forming ecoregions (blue). b, The intertropical convergence zone (ITCZ). The ITCZ was defined as regions that received a mid-summer (January (turquoise colour gradient) or July (red colour gradient)) mean monthly total rainfall of >20 cm, for the period 1979-2017. Where both January and July had rainfall of >20 cm, we show the measurement from the month with the largest total. The ITCZ is a strong predictor of the distribution of the tropical terrestrial ecoregions shown in b. Data sources are presented in Supplementary Table 1.

Vulnerability of tropical biodiversity
For each of the five vertebrate groups that have been comprehensively assessed by the International Union for the Conservation of Nature (IUCN) and for which spatial occurrence data are available, species classified as Vulnerable, Endangered or Critically Endangered are more dependent on the tropics than are those classified as Least Concern (Fig. 2b). In addition, 85% of species extinctions from these vertebrate groups have been of species that use the tropics. Consequently, although extinctions of other groups are less well understood, we can assume that most of an estimated 130,000 modern invertebrate extinctions will also have been of tropical species. Thus, not only are the tropics

mirrored by many forms of societal diversity. For example, tropical countries contain 40% of the world’s population yet 85% of extant languages are spoken within them. The tropics also provide incalculable benefits to humanity. They housed most of the key centres of plant domestication and have been a vital laboratory for the development of science itself – the disciplines of ecology, biogeography and evolutionary biology are founded on evidence gleaned from tropical ecosystems. Tropical ecosystems also make vital contributions to globally important ecosystem services. Although they cover just 0.1% of the ocean surface, coral reefs provide fish resources for the 275 million people that live within 30 km of them and coastal protection for up to 197 million people. Humid tropical forests cover less than 12% of the world’s ice-free land surface but produce 33% of global net primary productivity and store 25% of the carbon in the terrestrial biosphere, and tropical savannahs provide a further 30% of global net primary productivity and 15% of carbon storage. Tropical ecosystems also help drive vital atmospheric teleconnections. For instance, 70% of the rainfall in the 3.2-million-km² Rio de la Plata catchment is estimated to come from evaporation in Amazonia.

Vulnerability of tropical biodiversity
For each of the five vertebrate groups that have been comprehensively assessed by the International Union for the Conservation of Nature (IUCN) and for which spatial occurrence data are available, species classified as Vulnerable, Endangered or Critically Endangered are more dependent on the tropics than are those classified as Least Concern (Fig. 2b). In addition, 85% of species extinctions from these vertebrate groups have been of species that use the tropics. Consequently, although extinctions of other groups are less well understood, we can assume that most of an estimated 130,000 modern invertebrate extinctions will also have been of tropical species. Thus, not only are the tropics...
vastly more diverse than temperate regions, but this diversity is also at far greater risk from human actions. Moreover, given that the tropics have the highest proportion of species classified by the IUCN as Data Deficient and the lowest level of biodiversity-threat assessment information shortages mean we are probably underestimating the vulnerability of the tropical biome. We assessed this vulnerability in more depth by examining the effect of local and global stressors, the interactions between them and the resulting changes to tropical ecosystems.

Local stressors

The tropics are subject to some of the highest global rates of land-use change and degradation. Since 1990, while the spatial coverage of temperate forests has increased, tropical deforestation rates have exceeded five million hectares per year. Additional effects stem from the expansion of large infrastructure projects, such as dams, and the growing demand for agricultural commodities, biofuels, timber, wood for fuel, and other natural resources. All of these result in severe biotic responses. Even with mitigation, dams present a near-impassable barrier for river fish, and deforestation replaces a species-rich pool of forest specialists with a smaller pool of common open-area species.

The influence of land-use change also extends far into remaining natural areas through isolation and edge effects, additional anthropogenic disturbances and altered climatic conditions. Edge effects suppress areas through isolation and edge effects, additional anthropogenic forest specialists with a smaller pool of common open-area species.

Even with mitigation, dams present a near-impassable barrier for river fish and deforestation replaces a species-rich pool of forest specialists with a smaller pool of common open-area species. Edge effects suppress areas through isolation and edge effects, additional anthropogenic forest specialists with a smaller pool of common open-area species.

Pollution presents a diverse set of threats to tropical ecosystems. Inputs of sediment and nutrients from land-use change are well-established drivers of biodiversity loss across freshwater and coastal systems, including coral reefs. Pesticide use is increasing across the tropics, reflecting rapid intensification of farming practices and high pressures from pests on tropical crops. Tropical Asian rivers are a major source of the 1.2-2.4 million tonnes of plastic that enters the world’s oceans each year, with micro-plastics entering coral diet and larger debris increasing rates of coral disease. These examples of chronic pollution are exacerbated by extreme events such as the collapse of the Fundão Dam, which released about 50 million cubic metres of waste into a 600-km stretch of river in south-east Brazil and caused a 7,000-km2 toxic plume in the Atlantic Ocean.

Overexploitation is also pervasive across the tropics. Fishing has reduced fish biomass by over 75% across a third of coral reefs and is shrinking the mean body size of exploited freshwater taxa. Hunting has contributed to the loss of charismatic megafauna, extirpating African elephants, rhinoceroses and large predators from most of their original ranges. Tropical forests are affected by extensive over-harvesting of wildlife, with estimates of the annual harvests of highly trafficked animals such as pangolins reaching into the millions of individuals. Moreover, the growth in non-food uses of wildlife means that even small-bodied songbirds are at risk of global extinction.

Invasive species have been the second most important driver of vertebrate extinctions since AD 1500. Within terrestrial ecosystems, invasive species have exerted the strongest influence on islands and coastal mainland, causing thousands of species extinctions and altering trophic structures. On continents, invasive species currently have a greater effect on biodiversity in economically developed and extra-tropical regions, but tropical ecosystems are predicted to become increasingly vulnerable to invasion as the 21st century continues. Despite a deficit of research in the tropics, two prominent examples highlight the scope and magnitude of species invasions into terrestrial tropical ecosystems: there was an 84% increase in detections of alien species between 2003 and 2010 in Singapore, and invasive African grasses could threaten up to 380,000 km2 of Australia’s savannas by promoting landscape flammability.

In aquatic ecosystems, invasive predatory fish – such as the Indo-Pacific lionfish in Caribbean coral reefs or the Nile perch in African lakes – have contributed to the loss of native species. Marine invasions are also facilitated by the mass transport of species in the ballast water of ships, which results in widespread biotic homogenization.

Global climate change

Many of these local stressors are promoted by globalized drivers, but climate change is truly global. Increases in atmospheric CO2 concentrations to levels higher than 400 p.p.m. have important implications for tropical terrestrial and aquatic ecosystems. Ocean acidification from dissolved CO2 is changing ocean chemistry to the extent that declining coral calcification has already been detected. Conditions for reef accretion and growth may be mostly absent throughout the tropics by the year 2100 under ‘business-as-usual’ emission scenarios.
saddens, elevated CO₂ levels favor the growth of woody plants over grasses, contributing to woody encroachment and the potential for a switch in biome state. CO₂ fertilization may also have contributed to enhanced tree productivity and mortality rates observed in humid tropical forests. Higher temperatures also affect tropical vertebrates—e.g., by causing an extreme female bias in the sex ratio of green turtles in the warmer regions of the Great Barrier Reef and a reduction in the reproductive success of African wild dogs. Altered rainfall is also critical. Droughts are drying up biologically diverse small streams, and even modest changes in dry-season length increase tropical tree mortality and modify tropical forest bird community structure.

**Stressors affecting tropical species can interact in myriad ways.** We demonstrate this by compiling data from six case studies within a co-tolerance framework that enables the examination of species responses to two dominant stressors. Only a small subset of species or genera (8–32%) showed no or positive responses when both stressors were combined (Fig. 3), and up to 55% fell within the ‘double jeopardy’ quadrant that indicates a negative response to both stressors. Although our summary does not quantify the magnitude of effects, it clearly demonstrates that stressors can act together to reduce the abundance or occupancy of tropical species. Moreover, most tropical ecosystems are affected by more than two stressors at any given location and time, and co-tolerance analyses of this type are likely to underestimate the reality of human impacts.

Many changes to tropical ecosystems result from the indirect consequences of single or multiple stressors. On coral reefs, nutrient inputs from the land may increase susceptibility to coral bleaching, disease and outbreaks of pests, and pole-ward reef expansion is supported by feedbacks from range-shifts in tropical herbivorous fish. Overexploitation can result in surprising changes in tropical ecosystem properties through trophic cascades. For instance, the extirpation of a single detritivore fish species in the Orinoco basin reduced downstream organic-carbon transport, which in turn increased net primary productivity and respiration. On reefs, the overfishing of keystone predators has repercussions for benthic structure, and the removal of herbivores can limit coral recovery from mass-mortality events. In mesic savannas, changes to herbivore numbers alter ecosystem functions and structure through their interactions with wildfire regimes. Invasive species are also frequently linked to other stressors: the introduction of the Nile perch had a major role in the decline of endemic fish species in Lake Victoria, but these declines were also catalysed by a combination of other drivers including soil erosion, eutrophication and overfishing.

**Ecosystems in transition** Interactions between multiple anthropogenic stressors are causing pervasive changes in the tropics, such that alternative states are emerging across all major tropical ecosystems (Fig. 4). Perhaps counterintuitively, trees are encroaching on savannas and grasses are invading disturbed tropical forests—however, in both cases the changes are from species-rich to species-poor systems.

These marked ecosystem transitions are accompanied by widespread modification of species composition. For example, the relative abundance of coral species has been altered on reefs that maintain coral dominancy; the extirpation of native fish has followed species introductions in lakes; liana biomass has increased in otherwise undisturbed Neotropical forests; and patterns of plant regeneration in humid forests have been altered by the overharvesting of seed-dispersing vertebrates. Altered species composition is a cause for concern because it could signal the onset of more severe modification, especially if dominant species are vulnerable to other stressors or if there are cascading implications for ecosystem functioning. The collapse of Jamaican coral reefs provides one of the starkest examples. First, chronic overfishing depleted herbivorous fish populations, which left the system over-reliant on sea urchins for grazing algae. Then, in 1980, Hurricane Allen affected the system, creating a substantial amount of dead substrate. Although corals began to recover after the hurricane, the subsequent mass mortality of sea urchins owing to disease—combined with the fact that herbivorous fish were already at low levels of abundance—led to a phase shift from coral to macroalgal dominance.

**Interacting stressors and indirect effects** Stressors affecting tropical species can interact in myriad ways. We demonstrate this by compiling data from six case studies within a co-tolerance framework that enables the examination of species responses to two dominant stressors. Only a small subset of species or genera (8–32%) showed no or positive responses when both stressors were combined (Fig. 3), and up to 55% fell within the ‘double jeopardy’ quadrant that indicates a negative response to both stressors. Although our summary does not quantify the magnitude of effects, it clearly demonstrates that stressors can act together to reduce the abundance or occupancy of tropical species. Moreover, most tropical ecosystems are affected by more than two stressors at any given location and time, and co-tolerance analyses of this type are likely to underestimate the reality of human impacts.

is growing at a faster rate in the tropics than elsewhere (Fig. 5a), and by 2050 half of the world’s population will live in the tropics3. These demographic changes are accompanied by a steady growth in gross domestic product (GDP) that is linked in part to the rapid expansion of agricultural and extractive industries. However, in the tropics, per capita GDP – which is an important measure of human well-being – remains far lower than the non-tropical average (Fig. 5b) and the rates of change suggest that there has been little closing of the global inequality gap. Although the relationship between development and natural resource conservation does not have to be negative98,99, measures that reflect higher social performance are almost always associated with higher resource use100. A larger and more affluent tropical population will increase demands for timber, water, food, energy and land, all of which are strongly linked with environmental degradation.

These internal changes will be exacerbated by economic growth in non-tropical countries and the continued displacement of environmental effects to less-developed areas100. Indeed, despite high levels of tropical cultural diversity21,22, external socio-political influences (Fig. 5c, d) suggest that tropical countries have become increasingly susceptible to globalization. For example, the proportion of imported food crops (Fig. 5c) and foreign land acquisitions are far higher in the tropics than elsewhere (Fig. 5d) and are associated with extensive road building101 and agricultural investment102. These trends towards increasing tropical globalization are reinforced by changes in market integration (Fig. 5e, f) and technological development (Fig. 5g, h). For example, agricultural exports (Fig. 5f) are steadily increasing, albeit from a far lower baseline than the rest of the world. Moreover, given comparatively low levels of adoption of technological developments, such as industrial fishing techniques (Fig. 5g) or fertilizers (Fig. 5h), there is an enormous risk that the rate of natural resource extraction in many tropical countries will increase further, to supply both domestic and export markets103,104. Taken together, these examples highlight the crucial role that external markets will have in determining the fate of tropical ecosystems.

Effective environmental governance (Fig. 5i, j) is a necessary condition for improved sustainability outcomes105, particularly when domestic (Fig. 5a, b) and global (Fig. 5c-f) distal drivers are expected to exert increasing and unsustainable pressure on tropical ecosystems102. However, national-level assessments of governance effectiveness place the tropics far below extra-tropical countries, with no sign of improvement (Fig. 5i). External support for environmental governance may help where local governance is weak. Yet, despite the biological importance of the tropics, levels of environmental aid from the Organisation for Economic Cooperation and Development (OECD) are only marginally greater in the tropics than elsewhere (Fig. 5j), and these investments are dwarfed by the value of domestic resource extraction (for example, agricultural exports; Fig. 5f), the value of which is two orders of magnitude greater than overseas environmental aid. Furthermore, OECD environmental aid has been declining in recent years and seems unlikely to increase in the short term106.

Low governance capacity in the tropics is further exacerbated by insufficient research and development investment (Fig. 5k) and low levels of scientific output (Fig. 5l). Research investment is critical for driving innovation and the development of evidence-based solutions to environmental degradation103. Despite some notable centres of excellence, the vast majority of biodiversity-related data and research is concentrated in wealthy, non-tropical countries107, and manuscripts submitted by authors from low-income countries are less than half as likely to be published as those from high-income countries108. These trends highlight an alarming disconnect between the global scientific process and the people that are most capable of engaging with decision makers in tropical countries, who have the best understanding of local context and, arguably, have the strongest incentive to achieve positive outcomes for tropical conservation through their research.

**Socio-economic context and response capacity**

The interacting proximate stressors causing tropical environmental change are underpinned by broader changes in socio-economic and political factors. We examined the trajectories of four types of underlying distal drivers, including demography and the economy (Fig. 5a, b), socio-political factors (Fig. 5c, d), markets (Fig. 5e, f) and technology107 (Fig. 5g, h) to explore how tropical countries are changing relative to the rest of the world and to evaluate the relative influence of local and global drivers. We also examined how the capacity of tropical countries to reduce or cope with proximate stressors compares to non-tropical countries based on underlying governance systems (Fig. 5i, j) and research capacity (Fig. 5k, l).

The immense biodiversity of the tropics exists in the context of rapid demographic and economic growth (Fig. 5a, b). The human population

---

**Fig. 4 | Tropical ecosystems in transition.** a. Recurrent wildfires in historically fire-free humid tropical forests109 can lead to the dominance of grassy vegetation that impedes succession towards closed-canopy forests84,110. These wildfires result from the combination of local actions (for example, agricultural practices and logging) and climate change that has increased the prevalence of weather that promotes wildfires109, b. Chronic local pressures and acute climatic stressors can lead to coral cover being replaced by macroalgae, sponges or sediment-laden turf algae89,95. During the 1998 global coral-bleaching event, >90% of live coral died in the inner Seychelles and nearly half of the reefs transitioned to fleshy macroalgal regimes89. c. Woody encroachment is occurring in many savannahs84, causing biodiversity loss and altered system functioning88. Causes are mixed: regime shifts to forest-associated ecosystems have been attributed to fire suppression policies (for example, Brazilian cerrado (left) to forest (right)170), or changes in herbivory and increasing atmospheric CO₂69. d. The boom in hydropower dam construction is affecting large tropical river basins34. The transformation from lotic to lentic conditions reduces access to riparian and floodplain habitats that are nursery areas and feeding grounds for many of the species occupying higher trophic levels, leading to major shifts in species composition and ecosystem function35. Images from J.B. (a), N.A.J.G. (b), G. Durigan (c) and C.G.L. (d), used with permission.
a changing socio-economic context (Fig. 5). This changing context is characterized by growing and more affluent populations, an increasing globalization world, and weak governance and research capacity – all of which threaten to increase environmental degradation, conflict and inequality\(^{102}\). Countering these threats requires major improvements in local and global governance capacity and a step-change in how environmental objectives are integrated into broader development goals\(^{105}\).

We review the opportunities and limitations presented by three well-established and non-mutually exclusive approaches to conservation, before highlighting priorities for research.

**Conservation approaches**

A fundamental element of tropical conservation relies on protected areas to limit demographic pressures and the effect of local stressors. These are supported by a wealth of scientific evidence outlining the pervasive effect of local stressors across tropical ecosystems\(^{2,9}\) (Fig. 3) combined with an eco-centric philosophy that emphasizes the intrinsic rights of nature\(^{111}\). Despite a substantial expansion of protected area coverage in the marine and forested tropics\(^{112}\), the current network remains poorly designed, has very limited coverage of tropical freshwaters and grasslands, and is inadequately resourced\(^{113}\). Moreover, a strategy focused solely on protected areas may not foster environmental conservation outside of reserves\(^{114}\) and fails to engage with the distal drivers of biodiversity loss (Fig. 5) that can undermine the effectiveness of protected areas themselves\(^{115}\).

A second set of approaches for tropical conservation is based on the notion that people need to perceive the benefits of nature to justify conservation. These approaches emphasize the need to pursue conservation objectives in human-dominated landscapes, the provision of ecosystem services and the involvement of private-sector actors. In the tropics, they are epitomized by the growth in market-based conservation payment mechanisms, such as REDD+\(^{116}\), investments in the ‘blue economy’\(^{117}\) and a step-change in the number of companies making sustainability commitments\(^{118}\). These approaches have strengthened the conservation toolkit, especially where strict regulatory approaches have failed. Encouraging examples range from the positive effects of commodity certification (for example, palm oil\(^{119}\)) to payment for ecosystem service schemes (for example, watershed protection\(^{20}\)). However, such approaches also attract considerable criticism, with implementation often lagging behind commitments\(^{115}\), persistent concerns about the social legitimacy of compensation schemes\(^{121}\) and the misalignment of market-based mechanisms with local needs and perceptions of environmental values\(^{122}\).

A third and more diverse set of approaches is based on the recognition of the interdependencies between people and nature, the coevolution of ecological and socio-economic systems at local, regional and global scales\(^{123}\), and perspectives about the co-existence of people and nature. This set of ‘systems-based’ approaches includes: (1) an appreciation of the importance of bottom-up, community-based conservation approaches in human-dominated land- and seascapes (for example, small-scale fisheries\(^{124}\) and community-managed forests\(^{125}\)); (2) recognition of the role of indigenous people as environmental stewards and shifts towards an appreciation of more collective relationships with nature (for example, the Ecuadorian constitution\(^{26}\), the landscape- and ecosystem-wide approaches that attempt to bridge the role of actors working at different scales and in different sectors (for example, jurisdictional approaches to curb deforestation\(^{127}\)); and (4) a more explicit accounting of multi-scale feedbacks, including the role of distant market actors and distal drivers\(^{12}\). These broad, multi-layered ‘people and nature’ approaches hold considerable appeal but the inherent complexity of local contexts can make them challenging to conceptualize, implement and measure in joined-up and consistent ways\(^{128}\).

**Acting together and acting now**

The three approaches to the conservation and governance of tropical ecosystems outlined above are often associated with alternative researcher and practitioner worldviews\(^{129,130}\). However, the ecological diversity (Fig. 2a), vulnerability (Figs. 2b, 3) and socio-economic complexity (Fig. 5) of the tropics highlights the importance of pluralism\(^{131}\) and the need to adopt a variety of what are often complementary and synergistic approaches\(^{130}\). For all their deficiencies, protected areas are indispensable to limit the effect of local stressors, and it will be impossible to avoid further biodiversity loss unless they are strengthened and expanded\(^{132}\). However, conservation strategies must also address the underlying drivers of environmental change (Fig. 5) and avoid exacerbating deeply rooted inequalities\(^{114}\). Practice is always messier than theory, and the adoption of more sustainable management systems is usually only possible with the support of a range of actors, as can be seen in the recent successes of some hybrid governance approaches, with government, the private sector and civil society organizations all having vital roles\(^{133}\).

Another clear message is that conservation efforts need to operate at local, regional and global scales to be effective. Many distal drivers are disconnected in both space and time from the sites they affect, and the engagement of external actors – including in distant markets and governance processes – is often essential to ensure that local efforts are effective. These include more strategic integration of environmental policy with development goals\(^{34}\), the need for multi-
national environmental governance approaches, especially for aquatic systems, and recognition of the importance of tackling demand for unsustainable products from downstream buyers and investors. The capstone of such efforts lies in the urgent need to deliver on the Paris Agreement, without which climate change will undercut or even negate hard-won local conservation successes, whether in coral reefs or tropical forests.

Finally, we need to act now to address the pressing environmental challenges facing the tropics. This means being adaptive, learning by doing and embracing innovation. The past decades have seen a boom in proposals, innovations and insights about the governance and management of tropical ecosystems, ranging from more technocratic proposals to facilitate the evolution of climate-tolerant corals; ecological engineering to recover lost trophic interactions by species re-introductions, ecological replacements and rewilding; to radical new legal frameworks such as France’s loi de vigilance (2017-399; https://www.legifrance.gouv.fr/eli/loi/2017/3/27/2017-399/jo/texte) that places an unprecedented due diligence obligation on major companies to assess social and environmental risks in their supply chains that extend beyond French borders. Though these innovations serve different purposes and are varying scalable, they illustrate the potential of solutions-based science and conservation. Of course, acting now does not mean ignoring the existing evidence base or making uninformed decisions. Rather, it is vital that researchers and decision makers are vigilant to opportunities and risks and are willing to learn lessons.

**Keeping pace with the Anthropocene**

All approaches to governing tropical ecosystems will be more effective if they have local support and are based on strong scientific evidence that ensures, for example, that protected areas are located where they are most needed, ecosystem services are accurately quantified, extractive activities such as fishing and logging are managed sustainably, and underlying drivers of environmental degradation are identified and understood. Although these challenges are common to all conservation and sustainability science, they are magnified in the tropics owing to the unique diversity and high vulnerability of tropical ecosystems and the low research capacity of most tropical countries. Here we examine four areas in which research effort can be more closely aligned with some of the priorities highlighted by this review.

**Addressing key knowledge shortfalls**

Our understanding of tropical biodiversity is limited by substantial shortfalls in knowledge regarding taxonomy and species distributions. Overcoming these shortfalls will require targeting resources towards the data-scarce regions that cover so much of the tropics. At the ecosystem level, there is a need for increased study of structurally and functionally distinct systems, particularly tropical grassy biome, dry forests and low-order stream systems. Progress in these areas is likely to be aided by advances in DNA sequencing and informatics, which have the potential to invigorate taxonomic discovery, and by reaching across cultural divides to incorporate national, regional and local knowledge that often remains ignored because it is not available in English, included in standard databases or recognized by conventional science.

**Understanding vulnerability**

Our growing knowledge of the role of individual stressors, such as landscape configuration or overexploitation, needs to be complemented by research on the effect of multiple stressors, which could help predict and mitigate complex biotic responses when climate and local stressors act in concert (Fig. 3). Other phenomena that are important but harder to study include the role of time lags or extinction debts, trophic cascades and trajectories of ecosystem degradation and recovery in the face of unprecedented environmental change. Revealing these more-complex forms of vulnerability will often demand longer-term and larger multi-scale sampling and monitoring programs. New approaches are also needed to overcome one of the more intractable challenges of tropical ecology: the fact that we often know least about the rarest and most vulnerable species or taxonomic groups.

**Understanding distal drivers**

Conservation does not occur in a vacuum, and local interventions are likely to be much more effective if they are guided by a closer understanding of underlying distal drivers of biodiversity loss and environmental change, including identifying the actors behind such drivers, which will help to determine potential trigger points and identify more effective policy responses. Unpinching the role of distal drivers is essential to understand how distant interactions between social and environmental systems shape local environmental outcomes. Careful study has revealed many surprising interactions, such as links between the intensification of commercial fishing and increased bushmeat exploitation in west Africa, the role of warfare in driving African mammal declines or the role of currency exchange rates in driving deforestation. Achieving this deeper understanding requires greater integration of the natural and social sciences, with interdisciplinarity included as a core element of tropical conservation research.

**From research to impact**

Achieving positive effects from conservation research relies on building a stronger interface between science and society that challenges the oversimplified assumption of a linear flow from knowledge to action. Engendering positive changes will require closer participation of practitioners in the research process and investments in outreach activities and professional capacity building. These will be supported by studying the knowledge exchange process itself, including the critical part that is played by knowledge brokers and boundary organizations. Part of this process will require a focus on success stories or ‘bright spots’, which will enable the social, institutional and environmental conditions that create positive outcomes to be identified and replicated. The positive social and ecological outcomes from innovative restoration and rewilding programmes in Costa Rica and Mozambique demonstrate the potential for positive action.

Local managers and scientists have a vital role in designing and implementing research that can inform regionally appropriate conservation actions. At present, our knowledge of hyperdiverse ecosystems is over-reliant on inferences gleaned from distant research stations or inappropriate theoretical constructs developed for temperate context. Research is also more likely to have an effect if the spatial scale of studies is closely matched to the administrative scale at which resource decisions are taken. Sustaining research programmes and learning networks in study landscapes can help build vital relationships between researchers, local knowledge holders and decision makers.

Achieving these changes requires building on trends in the technological, disciplinary and cultural dimensions of research practice. In the technological domain, opportunities for data collection have been revolutionized by developments in remote sensing and drones, the plummeting costs of DNA technologies and the step-changes in bioinformatics that have enabled ‘big data’ to be stored and retrieved in open-access platforms. In the disciplinary domain, the past decade has seen a marked upward trend in interdisciplinary and transdisciplinary research and a greater – albeit still insufficient – integration of natural and social sciences. This has resulted in an increasing openness of researchers towards methodological pluralism and mixed-method approaches and a growing recognition of the contribution that can be made by local people and citizen- and para-scientists in biodiversity research. Changes in research culture include the greater internationalization of ecological science and closer approximation with society, both of which can help foster more fertile ground for knowledge exchange and capacity building. Notable advances include the development of multi-disciplinary and multinational learning networks, exponential growth in author teams and major syntheses such as the Intergovernmental Platform for Biodiversity and Ecosystem Services.

Recent years have seen an awakening of environmental consciousness and calls for decisive action that are manifest, for example, in the Paris Agreement, the Sustainable Development Goals and voluntary Zero Deforestation Commitments. Scientists from tropical and non-tropical regions can inform these endeavours by developing a reliable knowledge base and innovative management interventions. Overcoming the remaining research challenges is far from trivial and will require a massive investment of resources to develop scientific infrastructure.
and capacity within tropical nations, as well as profound changes to
