(Received 17 October 2007; published 24 January 2008)

This Letter describes the search for a new heavy charged gauge boson $W'$ decaying into an electron and a neutrino. The data were collected with the D0 detector at the Fermilab Tevatron $p\bar{p}$ Collider at $\sqrt{s} = 1.96$ TeV, and correspond to an integrated luminosity of about 1 fb$^{-1}$. Lacking any significant excess in the data in comparison with known processes, an upper limit is set on $\sigma_{W'} \times B(W' \rightarrow e\nu)$, and a $W'$ boson with mass below 1.00 TeV can be excluded at the 95% C.L., assuming standard-model-like couplings to fermions. This result significantly improves upon previous limits and is the most stringent to date.
The standard model (SM) describes the fundamental fermions and their interactions via gauge bosons at a high level of accuracy, but it is not considered to be a complete theory. Additional gauge bosons are introduced in, e.g., left-right-symmetric models [broken SU(2)L × SU(2)R] or in grand unified theories which may also involve supersymmetry (e.g., E6) [1]. Assuming the most general case, a new gauge group can comprise a new mixing angle $\xi$, new couplings to the fermions $\tilde{g}$, and a new Cabbibo-Kobayashi-Maskawa matrix $U'$. In some models the $W'$ boson ($W'^{+}$ or $W'^{-}$) is right-handed and decays therefore into a right-handed neutrino and a charged lepton. However, such a neutrino has not yet been observed.

In this Letter we make the assumption that there is no mixing, $\tilde{g}$ is equal to the SM coupling, $U'$ is equal to the SM Cabbibo-Kobayashi-Maskawa matrix, and that the decay channel $W' \rightarrow WZ$ is suppressed. Furthermore, the width $\Gamma_{W'}$ of the $W'$ boson is assumed to scale with its mass $m_{W'}$,

$$\Gamma_{W'} = \frac{4}{3} \frac{m_{W'}}{m_{W}} \Gamma_{W}. \quad (1)$$

The factor of 4/3 is applied in order to account for the decay into the third quark family (e.g., $W' \rightarrow t\bar{b}$) which is possible for $m_{W'}$ above the kinematic threshold for this process. In case of the existence of additional generations of fermions, it is assumed that they are too heavy to be produced by a $W'$ decay. This generic model has been introduced by Altarelli et al. [2]. It corresponds to the manifest left-right symmetric model [3] with light right-handed neutrinos if the $W'$ boson is right-handed. In this Letter, the general approach [2] is considered, where the additional gauge boson $W'$ can be right- or left-handed.

The $W'$ boson has been searched for previously by the D0 [4–6] and the CDF experiments [7–9] in various final states. The most restrictive limit so far is $m_{W'} > 800$ GeV at the 95% C.L. [5] reported by D0 ($W' \rightarrow q\bar{q}'$, Run I).

Data collected with the D0 detector [10] at the Fermilab Tevatron $p\bar{p}$ Collider at a center-of-mass energy of 1.96 TeV are analyzed for the production of $W'$ bosons and the subsequent decay into an electron and a neutrino. The neutrino cannot be detected, but it gives rise to missing transverse energy ($E_T$) in the detector. The data set corresponds to an integrated luminosity [11] of $0.99 \pm 0.06$ fb$^{-1}$ and was collected between 2002 and 2006 during Run II of the Tevatron.

Different SM processes contribute to the electron and $E_T$ final state: inclusive production of $W$ or $Z$ bosons, dibosons ($WW$, $WZ$, $ZZ$), or $t\bar{t}$ pairs in which at least one boson or one top quark decays into electrons directly or via tau decays. In these processes the missing energy is due to the neutrino. There are also two sources of misidentification background that can contribute to the electron and $E_T$ final state: QCD multijet background with one jet misidentified as an electron and energy mismeasurement which can cause large $E_T$ either along or in the opposite direction of the electron, and $Z \rightarrow ee$ events where one electron is lost (e.g., entering noninstrumented sections of the calorimeter) or reconstructed. The latter case can lead to large $E_T$.

The $W'$ signal and SM processes (including $Z \rightarrow ee$) have been simulated with the PYTHIA 6.323 [12] Monte Carlo program using the CTEQ6L1 [13] parton distribution functions (PDFs), except for the QCD multijet background, which is estimated from data. The generated events are passed through a detailed detector simulation based on GEANT [14], and they are combined with randomly triggered events from data to simulate the effects of pileup. Higher order corrections to the PYTHIA leading order cross sections ($K$ factors) have been applied. The next-to-next-to-leading order (NNLO) $K$ factors and errors due to PDF uncertainties for the signal, the $W$ and the $Z$ samples, are extracted from Ref. [15]; the NNLO (NLO) cross section for $t\bar{t}$ (di-boson) production is taken from Refs. [16] (Ref. [17]).

The signal cross section falls steeply with increasing mass of the $W'$ boson. In addition, for very large masses the on-mass-shell production of $W'$ bosons is heavily suppressed due to the smallness of the PDFs at large $x$. As shown in Fig. 1, the transverse mass distribution no longer exhibits a pronounced peak. The transverse mass $m_T$ is calculated from the transverse energy of the electron, $E_T$, the missing transverse energy, $E_{T \text{miss}}$, and the azimuth angle difference between the electron and $E_T$ via

$$FIG. 1 (color online). Transverse mass $m_T$ distributions for different masses of the $W'$ boson (generator level, PYTHIA). The event numbers correspond to an integrated luminosity of 1 fb$^{-1}$. $$

031804-4
\[ m_T = \sqrt{2E_{T}E_{\text{el}}[1 - \cos \Delta \phi(\text{electron}, \mathbf{E}_T)]}. \] (2)

Events triggered by a set of inclusive single electron triggers are considered. Electrons with \( E_{T} > 30 \text{ GeV} \) passing the offline identification criteria are selected. Monte Carlo studies have shown that the majority (=80\%) of the electrons stemming from the \( W' \) decays are emitted into the central detector region (CC, \( |\eta| < 1.1 \)). Since the forward detector region exhibits a small signal-to-background ratio, only electrons reconstructed in the CC are used in the analysis. Electromagnetic clusters are built around a calorimeter seed. Such clusters consist of cells in a cone \( \Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2} < 0.4 \) around the seed. Furthermore, the electron shower is required to be isolated in the calorimeter and to deposit most of its energy (>90\%) in the electromagnetic part of the calorimeter. The isolation \( I = [E_{\text{tot}}^{EM} - E_{\text{el}}^{EM}] / E_{\text{el}}^{EM} \), which uses the total shower energy, \( E_{\text{tot}}^{EM} \), in a cone of radius \( R = 0.4 \) and the electromagnetic energy, \( E_{\text{el}}^{EM} \), in a cone of radius \( R = 0.2 \), is required to be less than 0.2. A cut on the electron shower shape variable is applied to separate electromagnetic from hadronic showers. The electron is required to have a track matched in \( z \) and \( \phi \) direction and to stem from the primary vertex. Correction factors are applied to the simulated events in order to take differences in the reconstruction efficiencies observed in data and Monte Carlo events into account. Finally, the energy dependence of the basic electron reconstruction criteria has been studied with simulated electrons from \( W' \) decays. The reconstruction efficiency is found to be constant (94 ± 1\%) and does not exhibit a visible energy dependence within the statistical uncertainties of the Monte Carlo samples. The \( \mathbf{E}_T \) is calculated from all calorimeter cells. Corrections are applied to account for the electromagnetic and jet energy scales. We require \( \mathbf{E}_T > 30 \text{ GeV} \).

Since the transverse momentum of the neutrino is expected to be balanced by the electron transverse energy in signal events, a selection on the ratio of the energies is applied, \( 0.6 < E_{T}^{el} / \mathbf{E}_T < 1.4 \). This requirement reduces instrumental backgrounds from misidentified \( \mathbf{E}_T \). Jets are reconstructed with the iterative midpoint cone algorithm (\( R = 0.5 \)) [20]. If any jets with \( p_T > 15 \text{ GeV} \) are present in the event, we require \( \Delta \phi(\text{jet}, \text{electron}) < 2.8 \), and \( \Delta \phi(\text{jet}, \mathbf{E}_T) < 2.8 \). These selections remove events from QCD multijet production.

The contribution from QCD multijet events is estimated using a control sample derived from data with the same kinematic cuts. In this sample, the electron candidate fails the shower shape requirement. The resulting events are normalized to the data sample. The scale factor for the entire QCD multijet sample is adjusted in the low reconstructed transverse mass region \( (m_T < 30 \text{ GeV}) \), which is dominated by QCD multijet background events, such that the sum of the PYTHIA Monte Carlo prediction and the QCD multijet sample describes the data as shown in

Fig. 2(a). The data are normalized to $W$ boson production and decay in the $e\nu$ mode using the $W$ peak region [60 GeV $< m_T < 140$ GeV, as shown in Fig. 2(a)] because many efficiency and acceptance errors largely cancel in this ratio. We use the theoretical prediction for the $W$ boson production cross section $\sigma_W \times B(W \to e\nu) = 2583^{+84}_{-94}$ pb from Ref. [15].

Jets may be present in conjunction with a $W$ boson due to higher order QCD contributions. Since PYTHIA does not properly describe the transverse momentum distribution of the $W$ boson in such processes, this spectrum is separately reweighted in events with one, two, and three jets in order to match the distributions observed in the data. This correction affects 10% of the $W$ Monte Carlo events. The sample defined by the selection cuts mentioned above contains 452984 data events compared to 454000 ± 35000 events expected from SM processes and instrumental backgrounds after applying all corrections.

The tail of the spectrum ($m_T > 140$ GeV) is now considered to search for $W' \to e\nu$. A good agreement between the data and the background prediction can be observed as shown in Figs. 2(b) and 2(c). In the data 37 (2) events are reconstructed with $m_T > 300$ GeV (500 GeV) compared to a prediction of 37.1 ± 2.1(stat)$+6.0^{+10.5}_{-3.3}$(sys) [2.3 ± 0.5(stat)$+1.0^{+2.3}_{-0.5}$(sys)] background events. In Table I, the breakdown of the individual contributions of the various background processes is given, including expected numbers of signal events. Two kinds of systematic uncertainties contribute in this analysis (the relative uncertainties quoted below always relate to the tail of the transverse mass spectrum because only this region is used for the search). The uncertainties of the normalization in the $W$ peak region (4%), the cross sections of the SM processes (4%–10%), the electron reconstruction efficiency corrections (2%), and the scale factor for the QCD multijet sample (7%) affect only the global normalization. Uncertainties on the PDFs, electron energy scale and resolution, jet energy scale, decay width $\Gamma_W$ of the $W$ boson, and the transverse momentum of the $W$ boson lead to changes of the shape of the distributions.

In order to study the effect of the electron energy scale and resolution, the electron energies have been varied within the known uncertainties. The variations of scale and resolution are performed independently. The $E_T$ is recalculated after varying the electron energy. The overall uncertainty on the event numbers is large for the $W$ sample (4%), but small for the $W'$ signal (<1% for 500 GeV $< m_{W'} < 1200$ GeV). The uncertainty of the energy resolution is an order of magnitude smaller than the energy scale uncertainty. In order to study the PDF uncertainty, the Monte Carlo events which have been produced using CTEQ6L1 PDFs are reweighted to CTEQ6.1M.xx ($xx = 0, \ldots, 40$), making use of the CTEQ6.1M PDFs and the 40 error functions [13]. The overall uncertainty varies between 3% ($m_{W'} = 500$ GeV) and 8% ($m_{W'} = 1200$ GeV). For the $W$ sample an uncertainty of 3% is derived. The width of the $W$ boson is known to about 2% [21]. This can cause a shift (~4%) of the tail of the transverse mass distribution of the $W$ boson. Finally, the jet energy scale has been varied and the $E_T$ recalculated. The resulting uncertainty is below 1%.

Since we do not observe any significant excess in the data, an upper limit is set on the production cross section times branching fraction $\sigma_{W'} \times B(W' \to e\nu)$. The limit is derived using a binned likelihood for the whole transverse mass spectrum with 140 GeV $< m_T < 1000$ GeV. The in-
individual shape-changing systematic uncertainties (up and down variation) enter the limit calculation via individual histograms; bin correlations are taken into account. A Bayesian approach [22] is used to calculate upper limits on the cross section for different resonance masses. A Poisson distribution is assumed for the number of expected events in each bin of the transverse mass distribution, as well as flat prior probabilities for the signal cross sections. The prior for the combined signal acceptance and background yield is a multivariate Gaussian with uncertainties and correlations described by the corresponding covariance matrix. The observed and expected 95% C.L. limits on the production cross section times branching fraction $\sigma_{W'} \times B(W' \rightarrow e\nu)$ are shown in Fig. 3. The lower bound of the theoretical cross section is used to obtain the mass limit. Hence, an additional heavy charged gauge boson with mass below 1.00 TeV is excluded at the 95% C.L. In summary, a search for a new heavy charged gauge boson $W'$ decaying to an electron and a neutrino has been performed using 1 fb$^{-1}$ of data collected with the D0 detector in Run II. We do not observe an excess in the data, and we set upper limits on the cross section times branching fraction, which are of the order of 10−40 fb for $W'$ boson masses of 500 GeV < $m_{W'}$ < 1200 GeV. Further, a lower limit on the mass of the $W'$ boson is derived, assuming that the new gauge boson as introduced in [2] has the same couplings to fermions as the SM W boson. We exclude a $W'$ boson with $m_{W'} < 1.00 \text{ TeV}$ at the 95% C.L. This result represents the most stringent limit on the mass of a charged heavy gauge boson beyond the standard model to date.
