COMMUNICATION

Cross-Coupling of α-carbonyl sulfoxonium ylides with C–H bonds

Manuel Barday,[a] Christopher Janot,[b] Nathan R. Halcovitch,[b] James Muir,[c] and Christophe Aïssa*[a]

Abstract: The functionalization of carbon-hydrogen bonds in non-nucleophilic substrates using α-carbonyl sulfoxonium ylides has not been so far investigated, despite the potential safety advantages that those reagents would provide over diazo compounds or their in situ precursors. We describe the cross-coupling reactions of sulfoxonium ylides with C(sp³)–H bond of arenes and heteroarenes in the presence of a rhodium catalyst. The reaction proceeds by a succession of C–H activation, migratory insertion of the ylide into the carbon-metal bond and protodemetalation, the last step being turnover-limiting. The method is applied to the synthesis of benz[c]-acridines when allied to an iridium-catalyzed dehydrative cyclization.

Metal-catalyzed reactions of sulfoxonium ylides are rare and underexploited.[1] Specifically, the iridium-catalyzed formation of carbon-nitrogen and carbon-oxygen bonds from α-carbonyl sulfoxonium ylides has been optimized in industry in an effort to provide a safer alternative to the analogous diazo compounds, and thus avoid the risk of potential exothermic reactions linked to the release of nitrogen gas.[2] This issue is particularly relevant in the context of relatively large scale applications at a late stage of drug development, as illustrated in the multi-kilogram synthesis of MK-7246, a drug candidate with potential application against respiratory disease [Figure 1a].[3] Iridium carbene A [Figure 1b] is a likely intermediate of these reactions and was also postulated to account for the iridium-catalyzed synthesis of pyroles from α-carbonyl sulfoxonium ylides.[4] In this case, the formation of a carbon-carbon bond plausibly proceeds via electrophilic substitution by the reactive α,β-unsaturated β-amino-esters substrates.

In contrast to the transformation depicted in Figure 1b, the cross-coupling of sulfoxonium ylides with organometallic intermediates generated by activation of C–H bonds in less nucleophilic substrates has not yet been investigated. We hypothesized that after group-directed cyclo metallation involving metal-catalyzed C–H bond cleavage, B thus formed would undergo migratory insertion of α-carbonyl sulfoxonium ylides via intermediates C and/or D to give E. This intermediate would then liberate the cross-coupling products upon protodemetalation [Figure 1c]. Significantly, the realization of this design would address the potential safety issues of the recently reported group-directed C–H functionalization reactions with diazo compounds[5] and their in situ precursors such as triazoles[6] or hydrazones.[7] Moreover, it would complement the scope of recently reported rhodium-catalyzed annulation reactions with cyclopropanes[7] and enynes,[8] that also likely proceed by migratory insertion similar to the postulated evolution of D into E. Finally, it would also expand the scope of the well-established C–H insertion chemistry of metal-carbenoids generated from diazo compounds.[9]

Herein, we show that α-carbonyl sulfoxonium ylides undergo efficient cross-coupling reactions with C(sp³)–H bond of arenes and heteroarenes in the presence of a rhodium catalyst that do not require a sacrificial oxidizing reagent. Data from control experiment supports the sequence of steps depicted in Figure 1c. Thus, the cross-coupling reaction described herein is strongly distinct from the single previous example of C–H functionalization by α-carbonyl sulfoxonium ylides,[6] both in its scope and in terms of mechanism.

Figure 1. a) Iridium-catalyzed carbon-nitrogen bond formation from α-carbonyl sulfoxonium ylides. b) Postulated iridium-carbene intermediates from α-carbonyl sulfoxonium ylides during pyrole synthesis. c) Hypothetical cross-coupling of α-carbonyl sulfoxonium ylides with C–H bonds (this work).

We were mindful that the envisioned migratory insertion from B to E was not known for α-carbonyl sulfoxonium ylides. Thus, we initially focused our attention on known rhodium complex 1[10] (Cp* = 1,2,3,4,5-pentamethylcyclopentadienyl) and observed its reaction with ylide 2a to give a diastereomeric mixture of migratory

insertion complexes 3 and 4 in good yield [Eq. (1)]. The ratio of 3 and 4 varied from 2.8:1 to 5:1, depending on the duration of the purification by flash chromatography. Compounds 3 and 4 are configurationally stable in the solid state and in solution at room temperature. Their structure was confirmed by X-ray crystallography.[11]

Having established the crucial organometallic basis for the development of the catalytic reaction, we then observed that HFIP ([1,1,1,3,3,3-hexafluoro-2-propanol) was essential for the efficient protodemetalation leading to turnover and product formation [Eq. (2) and Tables S1–S3]. The reaction could proceed without added base, but its presence enabled to reach full conversion and led to higher yield of isolated products. Another important factor was the amount of ylide. Thus, the yield of 6b was quantitative when a 1.7 equiv of 2b was used (Cy = cyclohexyl), whereas using 2 equiv of bulkier 2a was necessary to reach full conversion and obtain 6a in 77% yield. The reaction did not proceed at all without [Cp*RhCl2], but its presence enabled to reach full conversion and obtain 6b in 81% in the presence of this catalyst and in the absence of AgSbF6. Attempts to replace the rhodium catalyst with [Cp*IrCl2], [Cp*CoI2], [Cp*Co(CO)2] or [Ru(p-cymene)OCl2], were unsuccessful.

Using ylides 2c–2k with 5 revealed that aryl ketones 6c and 6d were obtained in excellent yields, whereas ylides with less electron-rich substituents led to slightly (6e) or more markedly (6f) decreased yields of products [Figure 2]. Heteroaryl ketones 6g and 6h could also be obtained in excellent yields after a more prolonged reaction. Furthermore, ylides 2l–2k with a cyclopropane, protected piperidine or adamantyl R group all gave excellent yields of the desired products 6i, 6j, and 6k, respectively. Electronic effects have a great influence on the rate of the reaction, whereby both electron-donating and electron-withdrawing groups in para position to the cleaved C–H bond in 7 and 8[12] led to lower yields of 6i and 6m, as compared to 6b. The yield of 6i was not further optimized. However, the yield of 6m could be improved to 73% by performing the reaction at 90 °C. In addition, besides benzenic C–H bonds, the reaction was also amenable to the functionalization of heteroaromatic C–H bonds in 9–12.[13] Thus, indole 6n was obtained in very good yield, whereas mono-substituted pyrrole 6o was obtained in 75% yield. Bis-substitution at positions 2 and 5 was noticeable for 6p. Remarkably, furyl 6q was obtained in 63% yield as single regioisomer and without formation of doubly substituted product, whereas pyridin-2-one 6r was obtained in 71% yield under modified conditions. Finally, pyrazole, pyrimidine and methyloxime could also act as competent directing group although the reaction of 13–16[14] was more sluggish. Thus, it was necessary to increase the temperature to 90 °C in order to obtain 6s in 84% yield. On the other hand, 6t and 6v were obtained in good yield after incomplete conversion, whereas 6u was obtained in 93% yield. Replacing the rhodium and silver catalysts with the cationic rhodium complex [Cp*Rh(MeCN)3][SbF6]2 (8 mol%) was also necessary in order to isolate 6w in 90% yield. It is noteworthy that the primary alkylation products 6a–6w are obtained directly without requiring decarboxylation, in contrast to previous group-directed Rh(III)-catalyzed C–H functionalization reactions with diazo derivatives.[4c,13]

Figure 2. Rhodium-catalyzed cross-coupling of α-carbonyl oxosulfonium ylides with C(sp3)–H bonds. All yields given for isolated products after 17 h from 0.34 mmol of 2 (1.7 equiv) except otherwise noted. [a] No NaOAc. [b] 2.0 equiv of 2. [c] After 48 h. [d] After 24 h. [e] Ratio of regioisomers. [f] At 90 °C. [g] Yield of isolated product doubly substituted at positions 2 and 5. [h] Yield of recovered 11. [i] [Cp*Rh(OAc)3·H2O] (8 mol%) was used as rhodium catalyst without AgSbF6. [j] Yield of recovered 15. [k] [Cp*Ir(MeCN)3][SbF6]2 (8 mol%) was used as rhodium catalyst without AgSbF6. [l] Tran and cis methyl oximes (3:5:1)

The effect of substitution at the ylide carbon atom was investigated with compound 17. After 48 h at 90 °C, 85%
conversion was reached and 18 was isolated alongside unidentified impurities in 50% NMR yield [Eq. (3)]. This decreased reactivity could be explained by the increased bulkiness of 17.

![Chemical structure](image1)

Importantly, the C–H cross-coupling of sulfoxonium ylides described herein enables the rapid synthesis of valuable heterocycles. Thus, slightly modified conditions deliver 3-monomosubstituted N-methoxymethylacetamido 

![Chemical structure](image2)

After reaction of 19 and 2b [Eq. (4)]. Alternatively, the pyrimidine directing group that enabled the formation of 6u can be cleaved to give 21 [Eq. (5)]. Moreover, quinoline 23a was obtained in 77% yield by cross coupling of 22 and 2b and was then converted into benz[c]acidine 24a in one step and 60% yield. After treatment with a catalytic amount of [{Cp*RhCl}_2] in a mixture of isopropanol and water (Scheme 1). This iridium-catalyzed dehydrative cyclization was discovered whilst attempting the transfer hydrogenation of the quinoline moiety and likely proceeds via 1,4-dihydroquinoline F, followed by attack of the amine fragment on the ketone and rearomatization. Serendipitously, this two-step sequence was also amenable to the synthesis of 24b and 24c in good overall yields. Significantly, this approach offers an attractive alternative to the drastic conditions typically used for the synthesis of benz[c]acidines, a motif frequently explored in drug discovery.

Scheme 1. Reagents and conditions: a) See Figure 2; b) [{Cp*RhCl}_2] (4 mol%), i-PrOH/H_2O (9:5:0.5), air, 90 °C.

In a preliminary study of the mechanism of the C–H cross-coupling of sulfoxonium ylides, we could verify that using rhodium complexes [{Cp*RhCl}_2] (2 mol%), 1 (4 mol%), or 3 (4 mol%) as rhodium source under the optimized conditions led to similar yields of 6a (17–20% after 1 h, 72–77% after 17 h), which suggests that these rhodium complexes are all kinetically competent pre-catalysts of the reaction. We then attempted to garner further support for the catalytic cycle postulated in Figure 1c and made the following observations.

![Chemical structure](image4)

Figure 3. a) Deuterium labelling experiment. b) Reversibility of C–H cleavage. c) Kinetic isotope effect under catalytic conditions. d) Kinetic isotope effect in the protodemetalation of complex 3. Yields of isolated products. [a] After 1 h. [b] After 2 h.

First, we established that the C–H cleavage step is reversible. Thus, the reaction of 5 and 2b under the optimized conditions but in a mixture of 1,2-dichlorobenzene (1,2-DCB) and HFP-D ((CF_3)_2CHOH), led to an extensive incorporation of deuterium in recovered 5-D_6 and 6b-D_6 at the positions indicated in Figure 3a. Moreover, control experiments using 6b as substrate revealed that: i) the incorporation of deuterium at position β in 3a-D_6 can occur under the reaction conditions, and that ii) stirring 6b in 1,2-DCB/HFP-D at 60 °C for 16 h in the absence of any other reagent or catalyst is sufficient to enable deuterium incorporation in 6b at the enolizable positions. Furthermore, when treating 5-D_6 and 2b under the optimized conditions for 1–2 h, we observed an important loss of deuterium in recovered 5-D_6, even at low conversion, whereas isolated 6b did not contain deuterium [Figure 3b]. This result suggests that the C–H cleavage is not only reversible but also faster than the overall reaction leading to 6b.

Second, a kinetic isotope effect (k_D/k_H) was observed when comparing the reactivity of a mixture of 5 and 2b in the presence of HFP or HFP-D and a co-solvent (1,2-dichloroethane (1,2-DCE)). Thus, 6b and 6b-D_6 [10] were obtained after 2 h in 18% and 7% yield, respectively (k_D/k_H = 2.6 by initial conversion rates) [Figure 3c]. Similarly, in parallel experiments using complex 3, the yields of isolated 6a and 6a-D_6 [10] were 19% in 10%, respectively, (k_D/k_H = 1.9 by initial conversion rates) [Figure 3d], which is in good agreement with the value found under catalytic conditions.

Third, we were able to mimic the last step of the postulated catalytic cycle [15] and convert 3 into 6a and 1 in 83% and 70% yield, respectively, by treating a solution of 3 in HFP with 5 (5 equiv).
Overall, these results are in support of the reaction sequence postulated in Figure 1c, whereby the C–H cleavage would be irreversible and the protodemetalation turnover-limiting.

In conclusion, the cross-coupling described herein expands the traditional chemistry of sulfoxonium ylides[20] and brings these reagents into the realm of metal-catalyzed C–H activation.[21,22]
