#### Abstract

In this paper we consider the problem of decomposing a given integer matrix $A$ into an integer conic combination of consecutive-ones matrices with a bound on the number of columns per matrix. This problem is of relevance in the realization stage of intensity modulated radiation therapy (IMRT) using linear accelerators and multileaf collimators with limited width. Constrained and unconstrained versions of the problem with the objectives of minimizing beam-on time and decomposition cardinality are considered. We introduce a new approach which can be used to find the minimum beam-on time for both constrained and unconstrained versions of the problem. The decomposition cardinality problem is shown to be $\mathcal{N} \mathcal{P}$-hard and an approach is proposed to solve the lexicographic decomposition problem of minimizing the decomposition cardinality subject to optimal beam-on time.

Keywords: intensity modulated radiation therapy, multileaf collimator sequencing, field splitting, beam-on time, decomposition cardinality.

## 1 Introduction

In intensity modulated radiation therapy (IMRT), linear accelerators (linacs) (Figure 1) are used to deliver radiation to a target volume (the tumor tissue). The linac is mounted on a gantry which is able to rotate along a central axis while the patient is positioned on a couch that can rotate as well. In this way, it is possible to irradiate the patient from almost any angle. A number of radiation beams is selected and optimal fluence profiles for each beam are determined, which are represented as integer intensity matrices (IMs). The entries of an intensity matrix represent exposure times for particular bixels or beamlets of a radiation beam.

Figure 1: Medical linear accelerator from outside and inside. Images courtesy of Varian Medical Systems, Inc. All rights reserved.

Radiation passes through a multileaf collimator (MLC) (Figure 2) which realizes the fluence profile. The MLC consists of several pairs of identical tungsten alloy leaves. The leaves are positioned in opposing pairs and can move towards the opposing leaf or away from it to block or open the radiation beam. Thereby, the intensity of radiation can be individually controlled for each bixel, which is defined by an area of the radiation field the size of which is equal to the width of a leaf times the length of a minimal feasible move of the leaf. A beam shaping region (or aperture) can thus be created as shown in Figure 2. In this aperture, all areas not covered are irradiated with the same intensity. Because the dose delivered to the patient body is proportional to exposure time, by overlaying several apertures it is possible to form any intensity matrix. For more details on the planning process of IMRT please see Schlegel and Mahr [2002] and Ehrgott et al. [2008] and references therein. Example 1.1 shows how a multileaf collimator is used to create an IM of different intensities.

Example 1.1. If each of the light grey cells in Figure 3 corresponds to a radiation intensity of value one, and each of the dark grey cells corresponds to an intensity of value two then the overall intensity distribution can be modeled by the integer intensity matrix

$$
A=\left(\begin{array}{llll}
0 & 1 & 1 & 1 \\
1 & 1 & 2 & 0 \\
0 & 1 & 1 & 2 \\
1 & 1 & 0 & 0
\end{array}\right) .
$$

The planning process of intensity modulated radiation therapy involves three optimization problems: the optimal selection of the number and angle of the beam directions to be used (the beam angle or geometry optimization problem), the optimization of the fluence maps or intensity matrices for each chosen direction (the fluence map or intensity optimization problem) and finally, the collimator sequencing or realization problem. For an overview of optimization techniques used in IMRT planning we refer to Ehrgott et al. [2008]. In this paper we only discuss the realization problem. Therefore, we assume that the number and directions of the beams from which the patient is going to be irradiated are already fixed and that optimal intensity matrices for each of these beams are known. The realization problem is to find an efficient delivery sequence, i.e., a sequence of apertures via MLC adjustments to deliver the corresponding intensity matrix ensuring the best possible treatment. Throughout this paper we will consider step-and-shoot static IMRT where the radiation is turned off during the leaf adjustments, i.e., leaves do not move during irradiation.

Depending on the design of MLCs, there may be several technical constraints that have to be respected in the realization problem. In this paper, we consider the maximum leaf spread constraint and the interleaf collision constraint. The maximum leaf spread constraint restricts the maximum distance between opposing leaves, whereas the interleaf collision constraint restricts leaves to be positioned so that they do not overlap the opposing leaves in the adjacent rows.

Figure 3: Leaf positions of an MLC and intensity profiles.

Maximum leaf spread and field splitting. The mechanical design of MLCs restricts the allowable apertures since no leaf can have a larger distance from the vertical center line of the MLC than a certain threshold value. For example, size limits for Elekta and Varian MLCs are 12.5 cm and 15 cm , respectively [Chen et al., 2011]. Therefore, large intensity matrices (radiation fields) need to be split into several (adjacent) subfields, where the width of each subfield is not allowed to be larger than a given threshold value. There are two versions of this problem as stated by Chen et al. [2011]:

1. Splitting using vertical lines without overlapping of the subfields,
2. Splitting using vertical lines, allowing overlapping of the resulting subfields. In the literature this problem is often referred to as field splitting with feathering [ Wu et al., 2000, Liu and Wu, 2010].

In this paper, we focus on field splitting with feathering since the former can be considered as a special case of the latter.

Example 1.2. Consider the intensity matrix $A$ from Example 1.1,

$$
A=\left(\begin{array}{llll}
0 & 1 & 1 & 1 \\
1 & 1 & 2 & 0 \\
0 & 1 & 1 & 2 \\
1 & 1 & 0 & 0
\end{array}\right)
$$

Suppose that the maximum field width is three. Then, in order to realize the intensity profile we need to split it into at least two subfields. For example, we can split the intensity matrix
$A$ into two subfields

$$
A_{1}=\left(\begin{array}{lll}
0 & 1 & 0 \\
1 & 1 & 0 \\
0 & 1 & 0 \\
1 & 1 & 0
\end{array}\right), \quad A_{2}=\left(\begin{array}{lll}
0 & 1 & 1 \\
0 & 2 & 0 \\
0 & 1 & 2 \\
0 & 0 & 0
\end{array}\right),
$$

such that no overlapping of the subfields occurs, i.e., each entry of the matrix $A$ is covered by only one of the subfields:

$$
A=\left(\begin{array}{llll}
0 & 1 & 1 & 1 \\
1 & 1 & 2 & 0 \\
0 & 1 & 1 & 2 \\
1 & 1 & 0 & 0
\end{array}\right)
$$

where the light grey part represents $A_{1}$ and the dark grey part represents $A_{2}$.
On the other hand, if overlapping is allowed the desired intensities in the feathering region are represented by the sum of subfields in the feathering region. Consider the following split of $A$ into two subfields

$$
A_{1}=\left(\begin{array}{lll}
0 & 1 & 1 \\
1 & 1 & 0 \\
0 & 1 & 0 \\
1 & 1 & 0
\end{array}\right), \quad A_{2}=\left(\begin{array}{lll}
0 & 0 & 1 \\
0 & 2 & 0 \\
0 & 1 & 2 \\
0 & 0 & 0
\end{array}\right) .
$$

Then the desired intensity profile is achieved as

$$
A=\left(\begin{array}{llll}
0 & 1 & 1+0 & 1 \\
1 & 1 & 0+2 & 0 \\
0 & 1 & 0+1 & 2 \\
1 & 1 & 0+0 & 0
\end{array}\right),
$$

where the matrices $A_{1}$ and $A_{2}$ overlap in the third column of $A$ (colored grey) which is represented as the sum of the third and first column of the matrices $A_{1}$ and $A_{2}$, respectively.

Interleaf collision constraint. Some commercial MLCs restrict leaf positions in an aperture. More precisely, a leaf is not allowed to be positioned further than the opposing leaves in the adjacent rows. For example, leaf collision occurs in the last row of the second beam shape in Figure 3, where the right leaf is positioned further left than the opposing left leaf in the third row. This leaf configuration is allowed for some types of MLCs where interleaf collision is permitted, whereas for some types of MLCs it is not permitted. Figure 4 shows how the same aperture can be achieved without violating the interleaf collision constraints. Obviously, for some beam shapes we might need more than one leaf setting to avoid leaf collisions. MLC sequencing with leaf collision constraints is extensively studied in Kalinowski [2005] and Baatar et al. [2005]. In Section 2, we will briefly present the results relevant to this research.

Figure 4: Leaf positions of an MLC without leaf collision.

The realization problem has a great impact on the quality of the radiation treatment. The quality of the segmentation can be characterized by several features of the segmentation (see, e.g., Ehrgott et al. [2008], Lim and Lee [2008], Pardalos and Romeijn [2009], Chen et al. [2011]). In this paper we consider the total beam-on time and total number of shape matrices (see Definition 2.1). The total beam-on time represents the total amount of time a patient is exposed to radiation, whereas the number of shape matrices represents the total number of adjustments of the leaves (apertures) of the MLC required to deliver the IM. Although the realization problem is a multi-objective optimization problem, the algorithms that have been developed for sequencing with field splitting consider only beam-on time (see, e.g., the exact algorithms introduced by Kamath et al. [2007] and Chen et al. [2011]). Our paper will address the cardinality objective function in the sequencing problem with field splitting which, to the best of our knowledge, has never been discussed in the literature to date. We also consider the field splitting problem as a lexicographic optimization problem. Moreover, we extend our approach to MLCs with interleaf collision constraints, which also has not been covered in the existing literature. We would like to mention that some of this research originated in the Diploma thesis of Raschendorfer [2011].

The rest of the paper is organized as follows. Decomposition problems without field splitting are reviewed in Section 2. The decomposition problem with field splitting is discussed in Section 3, where we also propose our lexicographic optimization approach. We address the complexity of the problems with a single objective and introduce new formulations which can be used for both constrained and unconstrained versions of the problems. Section 4 presents numerical results. In Section 5 we summarize the contributions made by this article and give suggestions for further work.

## 2 MLC Sequencing without Field Splitting

In this section we review the most relevant results in the literature on MLC sequencing without field splitting. We will follow the notation used in Baatar et al. [2005].

Definition 2.1. An $m \times n$ matrix $Y=\left(y_{i, j}\right), i=1, \ldots, m, j=1, \ldots, n$ is called a consecutive ones matrix or a C1 matrix, if for each row $i, i=1, \ldots, m$, there exists an integer pair $\left[\ell_{i}, r_{i}\right)$, $\ell_{i}, r_{i} \in\{1, \ldots, n+1\}$, such that

$$
y_{i, j}= \begin{cases}1 & \text { if } \ell_{i} \leq j<r_{i} \\ 0 & \text { otherwise }\end{cases}
$$

i.e., the ones occur consecutively in a single block in each row.

Obviously, any aperture can be represented as a C1 matrix [Ahuja and Hamacher, 2004, Baatar et al., 2005, Ehrgott et al., 2008, Neumann, 2009] where ones and zeros represent the bixels where radiation is allowed to pass through or is blocked, respectively. The intervals [ $\ell_{i}, r_{i}$ ) can be interpreted as the left and right leaf positions, respectively, for the $i$ th pair of leaves. Totally blocked rows can be represented by any of the intervals $\left[\ell_{i}, r_{i}\right)$ with $\ell_{i}=r_{i}$. However, it is worth mentioning that they represent different leaf configurations. Some of the representations might not be valid for MLCs with interleaf collision constraint. For example, the second leaf configuration shown in Figure 3 is not valid for such MLCs since collision occurs between the left leaf in the third row and the right leaf in the fourth row. Hereafter, we refer to a C1 matrix as a shape matrix if it represents a valid leaf configuration. Let us denote the set of all C 1 matrices as $\mathcal{C}$. For the sake of brevity, we do not specify the dimension of the matrices which will be clear from the context.

Definition 2.2. Let $A \in \mathbb{Z}_{\geq 0}^{m \times n}$ and $\mathcal{C}^{\prime} \subseteq \mathcal{C}$. Then, a C1 decomposition with respect to $\mathcal{C}^{\prime}$ is defined by non-negative integers $\alpha_{k}$ and C 1 matrices $Y_{k}$ such that

$$
A=\sum_{Y_{k} \in \mathcal{C}^{\prime}} \alpha_{k} Y_{k} .
$$

Indeed, the realization problem is a decomposition problem: An integer matrix $A$ is decomposed into an integer conic combination of C1 matrices [Ahuja and Hamacher, 2004, Baatar et al., 2005, Ehrgott et al., 2008]. Coefficients $\alpha_{k}$ represent the beam-on time corresponding to the shape matrices $Y_{k}$ and are measured in monitor units (MU). The sum of the coefficients represents the total beam-on time and the number of non-zero coefficients represents the cardinality of the decomposition. The problem of minimizing the total beam-on
time $(B O T)$ can be formulated as

$$
\begin{array}{rlr}
\operatorname{BOT}(A)=\min \sum_{k=1}^{\left|\mathcal{C}^{\prime}\right|} \alpha_{k} & \\
(B O T) & \text { s.t. } \sum_{k=1}^{\left|\mathcal{C}^{\prime}\right|} \alpha_{k} Y_{k}=A, & \\
& \alpha_{k} \in \mathbb{Z}_{\geq 0}, & k=1, \ldots,\left|\mathcal{C}^{\prime}\right|, \\
Y_{k} & \in \mathcal{C}^{\prime}, & k=1, \ldots,\left|\mathcal{C}^{\prime}\right|,
\end{array}
$$

where $\mathcal{C}^{\prime}$ is the set of all admissible shape matrices and $\operatorname{BOT}(A)$ is the minimum total beamon time for a C 1 decomposition of the matrix $A$. This formulation can represent both versions of the problem, i.e., the problem with or without interleaf collision constraints. In the first case, the subset $\mathcal{C}^{\prime}$ corresponds to the set of all C 1 matrices which can represent beam shaping regions without violating the constraint. In the latter case, any C1 matrix is a shape matrix, i.e., $\mathcal{C}^{\prime}=\mathcal{C}$. From now on, to be short, we say the problem is unconstrained if there is no interleaf collision constraint and constrained otherwise.

In both versions of the problem, we have an exponential number of possible shape matrices. Thus, $(B O T)$ is a large scale integer program. However, this problem can be solved efficiently in linear time. There are different constructive exact algorithms available in the literature, see, for example, Baatar et al. [2005] and Engel [2005] for the beam-on time problem without interleaf collision constraint as well as Baatar et al. [2005] and Kalinowski [2005] for the constrained case. For the unconstrained problem, the minimum beam-on time can be obtained directly from the intensity matrix.

Theorem 2.3. [Engel, 2005, Baatar et al., 2005] For the unconstrained problem, i.e., $\mathcal{C}^{\prime}=\mathcal{C}$, the minimum total beam-on time is

$$
\begin{equation*}
B O T(A)=\max _{i=1, \ldots, m} \sum_{j=1}^{n+1} \max \left\{0, a_{i, j}-a_{i, j-1}\right\}, \tag{1}
\end{equation*}
$$

where $a_{i, 0}=a_{i, n+1}=0$ for all rows $i=1, \ldots, m$.
For the constrained problem, the relationship between the total beam-on time and shape matrices can be characterized using a pair of integer matrices:

Theorem 2.4. [Baatar et al., 2005] A matrix $A \in \mathbb{Z}_{\geq 0}^{m \times n}$ has a C 1 decomposition w.r.t. $\mathcal{C}^{\prime}$ with total beam-on time $\beta$ if and only if there exist $m \times(n+1)$ matrices $L=\left(\ell_{i, j}\right)$ and
$R=\left(r_{i, j}\right)$ with non-negative entries such that

$$
\begin{align*}
\ell_{i, j}-r_{i, j} & =a_{i, j}-a_{i, j-1}, & i=1, \ldots, m, j=1, \ldots, n  \tag{2}\\
\beta & =\sum_{j=1}^{n+1} \ell_{i, j}=\sum_{j=1}^{n+1} r_{i, j}, & i=1, \ldots, m,  \tag{3}\\
\sum_{j=1}^{k} \ell_{i-1, j} & \leq \sum_{j=1}^{k} r_{i, j}, & i=2, \ldots, m, k=1, \ldots, n+1,  \tag{4}\\
\sum_{j=1}^{k} \ell_{i, j} & \leq \sum_{j=1}^{k} r_{i-1, j}, & i=2, \ldots, m, k=1, \ldots, n+1, \tag{5}
\end{align*}
$$

where $a_{i, 0}=a_{i, n+1}=0$ for all rows $i=1, \ldots, m$.
Constraints (4) and (5) represent the interleaf collision constraints. Note that Theorem 2.4 is valid for MLCs without interleaf collision constraints, in which case we neglect constraints (4) and (5). Matrices $L$ and $R$ represent a set of C1 decompositions and a decomposition can be extracted in linear time (for more details see Baatar et al. [2005]).

The minimization of the number of shape matrices can be formulated as

$$
\begin{array}{rlrl}
D C(A)=\min \sum_{k=1}^{\left|\mathcal{C}^{\prime}\right|} \gamma_{k} & & \\
\text { s.t. } \sum_{k=1}^{\left|\mathcal{C}^{\prime}\right|} \alpha_{k} Y_{k} & =A, & & \\
\alpha_{k} & \leq M \gamma_{k}, & & k=1, \ldots,\left|\mathcal{C}^{\prime}\right|, \\
\alpha_{k} & \in \mathbb{Z} \geq 0, & k=1, \ldots,\left|\mathcal{C}^{\prime}\right|, \\
\gamma_{k} & \in \mathbb{B}, & k=1, \ldots,\left|\mathcal{C}^{\prime}\right|, \\
Y_{k} & \in \mathcal{C}^{\prime}, & k=1, \ldots,\left|\mathcal{C}^{\prime}\right|,
\end{array}
$$

where $M$ is a sufficiently large number, e.g., $M>\max \left\{a_{i j}: i=1, \ldots, m ; j=1, \ldots, n\right\}, \mathbb{B}$ represents the binary set $\{0,1\}$ and binary variables $\gamma_{k}$ are introduced to count the number of shape matrices used in a C 1 decomposition.

In the literature, the problem $(D C)$ is commonly referred to as minimum decomposition cardinality problem. We denote by $D C(A)$ the minimum number of shape matrices required in a C 1 decomposition of an integer matrix $A$.

Obviously, both the $(B O T)$ and $(D C)$ problems are feasible for any positive integer matrix $A$ and a feasible solution can be obtained easily. It is shown that the minimum decomposition cardinality problem is strongly $\mathcal{N} \mathcal{P}$-hard even for single-row [Baatar et al., 2005] and singlecolumn [Collins et al., 2007] matrices. Consequently, the ( $D C$ ) problem is strongly $\mathcal{N} \mathcal{P}$-hard for both constrained and unconstrained versions of the problem.

More generally, considering both beam-on time and decomposition cardinality as objectives to be minimized, the field segmentation problem can be presented as the following multicriteria optimization problem:

$$
\begin{array}{rlr}
\min \binom{\sum_{k=1}^{\left|\mathcal{C}^{\prime}\right|} \alpha_{k}}{\sum_{k=1}^{\left|\mathcal{C}^{\prime}\right|} \gamma_{k}} & \\
\text { s.t. } \sum_{k=1}^{\left|\mathcal{C}^{\prime}\right|} \alpha_{k} Y_{k} & =A, & \\
\alpha_{k} & \leq M \gamma_{k}, & k=1, \ldots,\left|\mathcal{C}^{\prime}\right|, \\
\alpha_{k} & \in \mathbb{Z}_{\geq 0}, & k=1, \ldots,\left|\mathcal{C}^{\prime}\right|, \\
\gamma_{k} & \in \mathbb{B}, & k=1, \ldots,\left|\mathcal{C}^{\prime}\right|, \\
Y_{k} & \in \mathcal{C}^{\prime}, & k=1, \ldots,\left|\mathcal{C}^{\prime}\right|,
\end{array}
$$

where the objectives represent the total beam-on time and the number of shape matrices. In the literature, a lexicographic optimization approach is proposed to find a Pareto optimal solution of the problem (see, for example, Baatar et al. [2005] and Kalinowski [2005]).

## 3 The Matrix Decomposition Problem with Field Splitting

Analogously to Section 2, MLC sequencing with field splitting can in general be formally presented as a multicriteria optimization problem. Let us introduce the notation [ $P]_{q}$ to represent a $m \times n$ matrix where columns $q$ to $q+w-1$ are represented by the matrix $P \in \mathbb{R}^{m \times w}$ and the remaining columns are all being 0 . Note that the matrix $P$ might have zero entries or even all zero columns. Using this notation, we can formally represent the multicriteria optimization problem for the matrix decomposition problem with field splitting as follows:

$$
\begin{array}{rlrl}
\min & \binom{\sum_{k=1}^{d} \sum_{t=1}^{\left|\mathcal{C}^{\prime}\right|} \alpha_{k t}}{\sum_{k=1}^{d} \sum_{t=1}^{\left|\mathcal{C}^{\prime}\right|} \gamma_{k t}} & & \\
\text { s.t. } A & =\sum_{k=1}^{d}\left[A_{k}\right]_{s_{k}} & & \\
A_{k} & =\sum_{t=1}^{\left|\mathcal{C}^{\prime}\right|} \alpha_{k t} Y_{t}, & & k=1, \ldots, d, \\
\alpha_{k t} & \leq M \gamma_{k t}, & k=1, \ldots, d, t=1, \ldots,\left|\mathcal{C}^{\prime}\right|, \\
A_{k} & \in \mathbb{Z}_{+}^{m \times w}, & k=1, \ldots, d, \\
s_{k} & \in\{1, \ldots, n\}, & k=1, \ldots, d, \\
\gamma_{k t} & \in \mathbb{B}, & k=1, \ldots, d, t=1, \ldots,\left|\mathcal{C}^{\prime}\right|, \\
\alpha_{k t} & \in \mathbb{Z}_{+}, & k=1, \ldots, d, t=1, \ldots,\left|\mathcal{C}^{\prime}\right|, \\
Y_{t} & \in \mathcal{C}^{\prime}, & & t=1, \ldots,\left|\mathcal{C}^{\prime}\right|,
\end{array}
$$

where $d$ is the number of subfields and $\left[A_{k}\right]_{s_{k}}$ represents a $m \times n$ matrix with columns from $s_{k}$ to $s_{k}+w-1$ represented by the matrix $A_{k}$ and the remaining columns all being 0 . Here $w$ is the maximum leaf spread. In other words, the matrix $A$ is split into $d$ submatrices with $w$ columns each, such that the C1 decompositions of the submatrices yield an as small as possible total beam-on time and decomposition cardinality. Note that the column indices $s_{k}$ are unknown and submatrices $A_{k}$ can be overlapping.

In the literature, the number of subfields is usually defined as $d=\left\lceil\frac{n}{w}\right\rceil$ (see, for example, Chen et al. [2011]) which we follow in this paper. In practice the number of subfields is two or three.

The field splitting problem, to the best of our knowledge, has never been considered as a multi-objective optimization problem or even as a single objective optimization problem with the cardinality objective even though both objectives are important in IMRT [Ehrgott et al., 2008]. Moreover, algorithms minimizing the beam-on time often produce a large number of shape matrices [Ehrgott et al., 2008]. We propose a lexicographic optimization approach to find a Pareto optimal solution of the problem $(F S)$. This Pareto optimal solution has a practical significance which can be interpreted as prioritization of reducing the total time a
patient is exposed to radiation and then decreasing the treatment time by minimizing the number of shape matrices within the given beam-on time. In this section we investigate the MLC sequencing problem with field splitting and develop related theory.

### 3.1 Minimization of Beam-on Time

There are several algorithms available in the literature for minimizing the beam-on time with field splitting with feathering region, for example, see Kamath et al. [2007] or Chen et al. [2011]. However, those algorithms are for the unconstrained version of the problem. In this section we develop a new approach which can be used for both the constrained and unconstrained versions of the problem. The minimization of beam-on time with field splitting can be formally presented as:

$$
\begin{aligned}
& \operatorname{FSBOT}(A)=\min \sum_{k=1}^{d} B O T\left(A_{k}\right) \\
& T) \\
& \text { s.t. } A=\sum_{k=1}^{d}\left[A_{k}\right]_{s_{k}}, \\
& A_{k} \in \mathbb{Z}_{+}^{m \times w}, \\
& s_{k} \in\{1, \ldots, n\},
\end{aligned} \begin{aligned}
& k=1, \ldots, d, \\
&
\end{aligned} \begin{aligned}
& k=1, \ldots, d
\end{aligned}
$$

Due to Theorem 2.4, each subfield $A_{k}$ can be presented by a pair of matrices $L^{k}$ and $R^{k}$. Moreover, minimum beam-on time of each subfield $A_{k}$ can be represented by the sum of entries in any row of the matrices. In this way, without considering the shape matrices explicitly, we can represent the beam-on time and interleaf collision constraints using the pair of matrices $L^{k}$ and $R^{k}$. However, we use a reformulation of Theorem 2.4 in terms of cumulative matrices derived from the pair of matrices $L^{k}$ and $R^{k}$. This leads us to a simpler formulation and proof of complexity of the ( $F S B O T$ ) problem with field splitting than applying the theorem directly.

For intensity matrix $A$, let us denote by $c_{i, j}^{\ell}$ and $c_{i, j}^{r}$ the row-wise cumulative sum of the entries of the matrices $L$ and $R$, respectively, i.e.,

$$
\begin{equation*}
c_{i, j}^{\ell}=\sum_{q=1}^{j} \ell_{i, q}, \quad c_{i, j}^{r}=\sum_{q=1}^{j} r_{i, q}, \quad \quad i=1, \ldots, m, j=1, \ldots, n+1 \tag{6}
\end{equation*}
$$

Then Theorem 2.4 can be restated in terms of cumulative sums $c_{i, j}^{\ell}$ and $c_{i, j}^{r}$ as follows.
Theorem 3.1. A matrix $A \in \mathbb{Z}_{+}^{m \times n}$ has a C 1 decomposition w.r.t. $\mathcal{C}^{\prime}$ with total beam-on time $\beta$ if and only if there exist $m \times(n+1)$ matrices $C^{\ell}=\left(c_{i, j}^{\ell}\right)$ and $C^{r}=\left(c_{i, j}^{r}\right)$ with
non-negative entries such that

$$
\begin{align*}
c_{i, j}^{\ell}-c_{i, j}^{r} & =a_{i, j}, & & i=1, \ldots, m, j=1, \ldots, n  \tag{7}\\
\beta & =c_{i, n+1}^{\ell}=c_{i, n+1}^{r}, & & i=1, \ldots, m,  \tag{8}\\
c_{i, j-1}^{\ell} & \leq c_{i, j}^{\ell}, & & i=1, \ldots, m, j=2, \ldots, n+1 \\
c_{i, j-1}^{r} & \leq c_{i, j}^{r}, & & i=1, \ldots, m, j=2, \ldots, n+1, \\
c_{i-1, j}^{\ell} & \leq c_{i, j}^{r}, & & i=2, \ldots, m, j=1, \ldots, n+1,  \tag{9}\\
c_{i, j}^{\ell} & \leq c_{i-1, j}^{r}, & & i=2, \ldots, m, j=1, \ldots, n+1 . \tag{10}
\end{align*}
$$

We have additional constraints (9) and (10) which ensure that the entries of the matrices $C^{\ell}$ and $C^{r}$ represent cumulative sums. The proof is evident from Theorem 2.4 and (6). The interleaf collision constraints are given by constraints (11) and (12). Theorem 3.1 is valid for the unconstrained problem as well, since we can just disregard the interleaf collision constraints in that case. Existence of matrices $C^{\ell}$ and $C^{r}$ represents the necessary and sufficient condition for existence of a C1 decomposition with total beam-on time of $\beta$ in a more compact form than matrices $L$ and $R$. Due to equations (6), matrices $L$ and $R$ can be obtained easily from matrices $C^{\ell}$ and $C^{r}$. Theorem 3.1 leads us to the following necessary and sufficient condition for decomposability in field splitting with respect to beam-on time.

Theorem 3.2. A matrix $A \in \mathbb{Z}_{\geq 0}^{m \times n}$ can be split into $d$ subfields $A_{k} \in \mathbb{Z}_{\geq 0}^{m \times w}$ with total beam on time $\beta$ if and only if there exist positions of the subfields $\left(s_{1}, \ldots, s_{d}\right)$ and pairs of matrices $C^{\ell k}$ and $C^{r k}, k=1, \ldots, d$, with non-negative entries such that

$$
\begin{array}{rlrl}
\beta & =\sum_{k=1}^{d} \beta_{k}, & \\
A & =\sum_{k=1}^{d}\left[C^{\ell k}-C^{r k}\right]_{s_{k}} & \\
\beta_{k} & =c_{i, w+1}^{\ell k}=c_{i, w+1}^{r k}, & k & \\
c_{i, j}^{r k} & \leq c_{i, j}^{\ell k}, & k & =1, \ldots, d, i=1, \ldots, m, \\
& j & =1, \ldots, w, i=1, \ldots, m, \\
c_{i, j-1}^{\ell k} & \leq c_{i, j}^{\ell k}, & k & =1, \ldots, d, i=1, \ldots, m, \\
& & j=2, \ldots, w+1, \\
c_{i, j-1}^{r k} & \leq c_{i, j}^{r k}, & k & =1, \ldots, d, i=1, \ldots, m, \\
c_{i-1, j}^{\ell k} & \leq c_{i, j}^{r k}, & j & =2, \ldots, w+1, \\
& k & =1, \ldots, d, i=2, \ldots, m, \\
c_{i, j}^{\ell k} & \leq c_{i-1, j}^{r k}, & j & =1, \ldots, w+1, \\
& k & =1, \ldots, d, i=2, \ldots, m, \\
& j & =1, \ldots, w+1,
\end{array}
$$

Proof. Apply Theorem 3.1 for each subfield $A_{k}$.

Then the problem (FSBOT) can be represented in terms of the cumulative matrices as

$$
\begin{array}{ll}
\min & \sum_{k=1}^{d} \beta_{k} \\
\text { s.t. } & (14)-(20) \\
& c_{i, j}^{\ell k}, c_{i, j}^{r k}, \beta_{k} \in \mathbb{Z}_{\geq 0}, k=1, \ldots, d, i=1, \ldots, m, j=1, \ldots, w+1, \\
& s_{k} \in\{1, \ldots, n\}, k=1, \ldots, d .
\end{array}
$$

$\left(F S B O T^{\prime}\right)$ can be used for both constrained and unconstrained versions of the problem. For the unconstrained case we have to remove constraints (19) and (20) which represent the interleaf collision constraints. Some of the constraints in the formulation are redundant and can be removed or reformulated to make the formulation compact and tighter. However, we keep the formulation as it is stated in order to avoid complicated notations and make it easier to follow the main ideas.

The state-of-the-art exact algorithms proposed by Kamath et al. [2007] and Chen et al. [2011], for unconstrained beam-on time minimization, consider all possible positions of the subfields and for any fixed positions an optimal split is obtained using constructive algorithms. In this paper we follow the same exhaustive approach to find the minimum beam-on time and corresponding positions of the subfields.

For any fixed positions $s=\left(\bar{s}_{1}, \ldots, \bar{s}_{d}\right)$ of the subfields the corresponding integer program $\left(F S B O T^{\prime}\right)$ can be solved efficiently. Indeed, the feasible set is an integral polyhedron.

Theorem 3.3. For any fixed positions of the submatrices the problem (FSBOT') can be solved in polynomial time.

Proof. We provide a sketch of the proof. We show that for any fixed positions $s=\left(\bar{s}_{1}, \ldots, \bar{s}_{d}\right)$ of the subfields the corresponding feasible set defined by constraints (14) to (20) is an integral polyhedron. The coefficient matrix provided by (14) to (20) can be represented by a block matrix $\left[\tilde{C}^{\ell} \tilde{C}^{r}\right]$ where $\tilde{C}^{\ell}$ and $\tilde{C}^{r}$ represent coefficients corresponding to the variables $c_{i, j}^{\ell k}$ and $c_{i, j}^{r k}$, respectively. Consider any subset $J^{\ell}$ of columns of the matrix $\tilde{C}^{\ell}$. One can show that the set $J^{\ell}$ can be partitioned into two subsets $J_{1}^{\ell}$ and $J_{2}^{\ell}$ such that the following inequality holds for any row $i$ of the matrix $\tilde{C}^{\ell}$ :

$$
0 \leq \sum_{j \in J_{1}^{\ell}} \tilde{c}_{i, j}^{\ell}-\sum_{j \in J_{2}^{\ell}} \tilde{c}_{i, j}^{\ell} \leq 1
$$

Note that each row of the matrix $\tilde{C}^{\ell}$ has at most two non-zero entries. The same statement is true for the block matrix $\tilde{C}^{r}$. Then, the proof immediately follows from the well known Ghouila-Houri characterization of total unimodularity [Ghouila-Houri, 1962].

### 3.2 Decomposition Cardinality

In this section we consider the field splitting problem with the decomposition cardinality objective.

Theorem 3.4. The minimum decomposition cardinality problem with with field splitting is a strongly $\mathcal{N} \mathcal{P}$-hard problem even for a single row intensity matrix and field splitting without feathering.

Proof. Let us consider a row intensity matrix

$$
A=\left(a_{1}, a_{2}, \ldots, a_{w}, 0, \ldots, 0, a_{2 w}\right) \in \mathbb{Z}^{2 w}
$$

with the last $w$ entries being 0 except for the very last entry. Obviously, $d=2$ and the matrix must be split as

$$
A=\left[\left(a_{1}, a_{2}, \ldots, a_{w}\right)\right]_{1}+\left[0, \ldots, 0, a_{2 w}\right]_{w+1} .
$$

The second matrix can be realized using a single shape matrix. Thus, finding the decomposition with minimum number of shape matrices for the single row matrix $A$ with field splitting is equivalent to finding a decomposition with minimum number of shape matrices of the row matrix $\left(a_{1}, a_{2}, \ldots, a_{w}\right)$, which is strongly $\mathcal{N} \mathcal{P}$-hard [Baatar et al., 2005].

Therefore, the minimum decomposition cardinality problem with field splitting is strongly $\mathcal{N} \mathcal{P}$-hard for both constrained and unconstrained versions of the problem even for fixed positions of the submatrices.

Using constraints with big M , as in ( $F S$ ), one can formulate the decomposition cardinality problem with field splitting as an integer program. However, it is well known that big M constraints lead to poor LP relaxations. Therefore, we look for an alternative formulation without the big M constraints. This can be achieved due to the following necessary and sufficient condition for decomposability with respect to the number of shape matrices for a single field which characterizes the relationship between decomposition cardinality and beamon time.

Theorem 3.5. An intensity matrix $B \in \mathbb{Z}_{\geq 0}^{m \times n}$ can be realized using $p$ shape matrices if and only if for some $q$ there exists a decomposition

$$
\begin{equation*}
B=\sum_{k=1}^{q} \alpha_{k} B_{k} \tag{21}
\end{equation*}
$$

with $\alpha_{k} \in \mathbb{Z}_{\geq 0}, \quad B_{k} \in \mathbb{Z}_{\geq 0}^{m \times n}, k=1, \ldots, q$, such that

$$
\begin{equation*}
p=\sum_{k=1}^{q} B O T\left(B_{k}\right) . \tag{22}
\end{equation*}
$$

Proof. If $B$ can be realized using $p$ shape matrices, i.e.,

$$
B=\sum_{k=1}^{p} \alpha_{k} S_{k}
$$

then by choosing $q=p$ and $B_{k}=S_{k}, k=1, \ldots, p$ we get the decomposition.
Suppose, for some $q$, there is a decomposition of $B$

$$
B=\sum_{k=1}^{q} \alpha_{k} B_{k}
$$

with

$$
p=\sum_{k=1}^{q} B O T\left(B_{k}\right)
$$

For each matrix $B_{k}, k=1, \ldots, q$, consider a realization

$$
B_{k}=\sum_{j=1}^{B O T\left(B_{k}\right)} S_{k j}
$$

Then the matrix $B$ can be represented as an integer linear combination of $p$ shape matrices as

$$
B=\sum_{k=1}^{q} \alpha_{k} \sum_{j=1}^{B O T\left(B_{k}\right)} S_{k j}
$$

Note that $q$, the number of matrices, is not fixed in Theorem 3.5. Moreover, some of the shape matrices might be used several times. From Theorem 3.5 the following characterizations of the decompositions with smallest cardinality can immediately be deduced.

Corollary 3.6. Let $p$ be the minimum decomposition cardinality of $B$.

1. The following statements are true for any decomposition $B=\sum_{k=1}^{q} \alpha_{k} B_{k}$ with $p=$ $\sum_{k=1}^{q} \operatorname{BOT}\left(B_{k}\right)$, where $\alpha_{k} \in \mathbb{Z}_{\geq 0}, k=1, \ldots, q$.
(a) $B_{k} \neq B_{h}$ for all $k \neq h, k, h=1, \ldots, q$.
(b) For any realizations of the matrices

$$
B_{k}=\sum_{j=1}^{q_{k}} \gamma_{k j} S_{k j} \text { with } \operatorname{BOT}\left(B_{k}\right)=\sum_{j=1}^{q_{k}} \gamma_{k j}, k=1, \ldots, q,
$$

- $D C\left(B_{k}\right)=\operatorname{BOT}\left(B_{k}\right)$, i.e., $\gamma_{k j}=1$ for all $k=1, \ldots, q, j=1, \ldots, q_{k}$;
- $S_{k j} \neq S_{h t}$ for all $k \neq h, k, h=1, \ldots, q$ and $j=1, \ldots, q_{k}, t=1, \ldots, q_{t}$.

2. There always exists a decomposition of $B$ which satisfies the conditions in 1 . and

$$
\alpha_{k} \neq \alpha_{h}
$$

for all $k \neq h, k, h=1, \ldots, q$.
Corollary 3.6 characterizes well the decompositions of a matrix $B$ with the smallest cardinality. Moreover, it provides the opportunity to express the decomposition cardinality of a matrix by the sum of minimum beam-on times of the matrices used in the decomposition (21). In other words, the decomposition cardinality problem is equivalent to the decomposition of the intensity matrix into an integer conic combination of integer matrices such that the sum of total beam-on times of the integer matrices are minimized. The necessary and sufficient condition can be extended for the field splitting problem as follows.

Theorem 3.7. An intensity matrix $A \in \mathbb{Z}_{\geq 0}^{m \times n}$ can be split into $d$ submatrices $A_{k} \in \mathbb{Z}_{\geq 0}^{n \times w}$ which can be realized using $p$ shape matrices in total if and only if there exist positions $\left(s_{1}, \ldots, s_{d}\right)$ such that for some $q_{1}, \ldots, q_{d}$ we have

$$
\begin{aligned}
A & =\sum_{k=1}^{d} \sum_{z=1}^{q_{k}} \alpha_{k z}\left[B_{k z}\right]_{s_{k}}, \\
p & =\sum_{k=1}^{d} \sum_{z=1}^{q_{k}} B O T\left(B_{k z}\right)
\end{aligned}
$$

with $\alpha_{k z} \in \mathbb{Z}_{\geq 0}, \quad B_{k z} \in \mathbb{Z}_{\geq 0}^{m \times w}$ for all $k=1, \ldots, d, z=1, \ldots, q_{k}$.
We leave the proof to the reader. It can be done in the same manner as the proof of Theorem 3.5. Moreover, if $p$ is the minimum cardinality then Corollary 3.6 holds for any submatrix $B_{k z}$.

Based on Theorem 3.7, the decomposition cardinality problem with field splitting can formally be stated as

$$
\begin{array}{rlrl}
\min & \sum_{k=1}^{d} \sum_{z=1}^{q_{k}} B O T\left(B_{k z}\right) & \\
(F S D C) & \text { s.t. } A & =\sum_{k=1}^{d} \sum_{z=1}^{q_{k}}\left[z B_{k z}\right]_{s_{k}}, & \\
\\
B_{k z} & \in \mathbb{Z}_{\geq 0}^{m \times w}, & z=1, \ldots, q_{k}, k=1, \ldots, d, \\
s_{k} & \in\{1, \ldots, n\}, & k=1, \ldots, d .
\end{array}
$$

where $q_{k}$ is the number of different values of the coefficients of the matrices $B_{k z}$ in the integer decomposition of the matrix $A_{k}$. The number of different values $q_{k}$ can be determined by the
largest possible entry of the matrix $A_{k}$ and the coefficients of the matrices $B_{k z}$ must be in the range $0 \leq z \leq q_{k}$.

Further, due to Theorem 3.1, we can represent each subfield $B_{k z}$ and the minimum beamon time $B O T\left(B_{k z}\right)$ by a pair of matrices $C^{k z l}$ and $C^{k z r}$, which leads us to the following formulation of the problem:

$$
\begin{align*}
\min \sum_{k=1}^{d} \sum_{z=1}^{q_{k}} \beta_{k z} & \\
\left(F S D C^{\prime}\right) \quad \text { s.t. } A=\sum_{k=1}^{d} \sum_{z=1}^{q_{k}} z\left[\left(C^{k z l}-C^{k z r}\right)\right]_{s_{k}}, &  \tag{23}\\
\beta_{k z}=c_{i, w+1}^{k z l}=c_{i, w+1}^{k z r}, & i=1, \ldots, m, z=1, \ldots, q_{k},  \tag{24}\\
& k=1, \ldots, d, \\
c_{i, j}^{k z r} \leq c_{i, j}^{k z l}, & i=1, \ldots, m, j=1, \ldots, w,  \tag{25}\\
& z=1, \ldots, q_{k}, k=1, \ldots, d,  \tag{26}\\
c_{i, j-1}^{k z l} \leq c_{i, j}^{k z l}, & i=1, \ldots, m, j=2, \ldots, w+1,  \tag{27}\\
& z=1, \ldots, q_{k}, k=1, \ldots, d,  \tag{28}\\
c_{i, j-1}^{k z r} \leq c_{i, j}^{k z r}, & i=1, \ldots, m, j=2, \ldots, w+1, \\
& z=1, \ldots, q_{k}, k=1, \ldots, d, \\
c_{i-1, j}^{k z l} \leq c_{i, j}^{k z r}, & i=2, \ldots, m, j=1, \ldots, w+1, \\
& z=1, \ldots, q_{k}, k=1, \ldots, d, \\
c_{i, j}^{k z l} \leq c_{i-1, j}^{k z r}, & i=2, \ldots, m, j=1, \ldots, w+1, \\
& z=1, \ldots, q_{k}, k=1, \ldots, d, \\
& i=1, \ldots, m, j=1, \ldots, w+1, \\
c_{i, j}^{k z l}, c_{i, j}^{k z r}, \beta_{k z} \in \mathbb{Z}_{\geq 0}, & z=1, \ldots, q_{k}, k=1, \ldots, d, \\
& k=1, \ldots, d .
\end{align*}
$$

Note that, for any optimal solution of (FSDC'), the submatrices $C^{k z l}$ and $C^{k z r}$ define a matrix $B_{k z}$ for which $B O T\left(B_{k z}\right)=D C\left(B_{k z}\right)$. Thus, any algorithm for minimizing beam on time can be used to extract the actual shape matrices for each subfield $B_{k z}$. For example, we can use the algorithm proposed in [Baatar et al., 2005] to extract the shape matrices from the matrices $C^{k z l}$ and $C^{k z r}$ which can be done in linear time.

### 3.3 Lexicographic Optimization

We use a lexicographic approach to find a Pareto optimal solution of $(F S)$, i.e., first we minimize the total beam-on time and then the total number of shape matrices with respect to the minimum beam-on time. The minimum beam-on time can be obtained efficiently by solving a finite number of linear programs, as proposed in Section 3.1. However, not
all optimal solutions of (FSBOT) lead us to a Pareto optimal solution of the field splitting problem $(F S)$. This can be demonstrated by the following example.

Example 3.8. Consider a field splitting problem with $w=5, d=2$ and a single row intensity matrix

$$
A=\left(\begin{array}{llllllll}
1 & 1 & 1 & 1 & 1 & 2 & 2 & 2
\end{array}\right)
$$

Obviously, there is only one possible position for the subfields, precisely $s_{1}=1$ and $s_{2}=4$. Moreover, one can easily see that the minimum beam-on time is three for the field splitting with $w=5$. The matrix $A$ can be split in two different ways such that minimum beam-on time is achieved:

$$
\begin{aligned}
& \left(\begin{array}{llllllll}
1 & 1 & 1 & 1 & 1 & 2 & 2 & 2
\end{array}\right)=\left[\begin{array}{lllll}
1 & 1 & 1 & 0 & 0
\end{array}\right]_{1}+\left[\begin{array}{lllll}
1 & 1 & 2 & 2 & 2
\end{array}\right]_{4} \\
& \left(\begin{array}{llllllll}
1 & 1 & 1 & 1 & 1 & 2 & 2 & 2
\end{array}\right)=\left[\begin{array}{lllll}
1 & 1 & 1 & 1 & 1
\end{array}\right]_{1}+\left[\begin{array}{lllll}
0 & 0 & 2 & 2 & 2
\end{array}\right]_{4}
\end{aligned}
$$

The total minimum beam-on time for both cases is three. However, we need three and two shape matrices, respectively, to achieve the minimum beam-on time.

Therefore, in order to find a Pareto optimal solution we have to consider all subfield positions at which the minimum total beam-on time $\beta^{*}$ is achieved. In other words, we have to solve the following integer program for each $s^{*}$ that yields the minimum beam-on time:

$$
\begin{aligned}
& \min \sum_{k=1}^{d} \sum_{t=1}^{\left|\mathcal{C}^{\prime}\right|} \gamma_{k t} \\
&\left(F S D C\left(s^{*}\right)\right) \quad \text { s.t. } \sum_{k=1}^{d} \sum_{z=1}^{q_{k}} z \beta_{k z}=\beta^{*}, \\
&(23)-(30) .
\end{aligned}
$$

Note that we are using only the subfield positions but not the actual subfields that provide the minimum beam-on time $\beta^{*}$.

## 4 Numerical Results

We tested our approach using CPLEX 12.6 embedded in C++ on a Linux machine with 32 Gb RAM, Intel Xeon 6 core, 3.5 GHz . We used 47 clinical examples varying in size from 5 to 23 rows and 6 to 30 columns, with the maximum intensity level $a_{\text {max }}$ varying between 9 and 40 (instances $1-17$ and $33-62$ in Table 1). In addition, we used 15 instances of size $10 \times 10$ with entries randomly generated between 1 and 14 (instances $18-32$ in Table 1). For all instances we considered four versions of the field splitting problem with feathering regions - splitting the intensity matrix into two and three subfields, i.e., $d=2$ and $d=3$, for the constrained and unconstrained cases. To be concise, we refer to the problems with $d=2$ and $d=3$ as two and three splitting, respectively. Table 1 shows the size and maximum intensity levels of the intensity matrices as well as the number of subfields, width and number of possible splitting positions for the subfields. We did not include the number of possible splitting positions for the two splitting problem since for each instance there is a unique set of positions for the subfields. In Table 1, the instances are listed in lexicographically increasing order according to $(w, n, m)$ and file name. The entire data set is available at http://dx.doi.org/10.17635/lancaster/researchdata/211.

### 4.1 Minimizing Beam-on Time

First we tested our proposed LP based approaches for constrained and unconstrained versions of the $\left(F S B O T^{\prime}\right)$ problems. The computational results are shown in Table 2. Each instance of the $\left(F S B O T^{\prime}\right)$ problem was solved in less than one second. In three splitting, for some instances the minimum beam-on time was achieved for several sets of subfield positions. For example, for instance 62 the minimum beam-on time was achieved for 4 and 10 different sets of subfield positions for the constrained and unconstrained versions of three splitting, respectively. Each set of positions that provided the minimum beam-on time was then used as a candidate set of positions for the subfields in the lexicographic approach.

### 4.2 Minimizing Beam-on Time and Decomposition Cardinality

The main purpose of the numerical study was to test the method for two and three splitting with feathering region in both the unconstrained and constrained case when both objectives beam-on time and cardinality are considered. To the best of our knowledge, there is no existing algorithm which does that. So we compared our lexicographic approach with another approach, which is based on the following idea that once the subfields are obtained we can use single field sequencing algorithms to produce the shape matrices for each subfield. We implemented two versions of this approach that we compared with the lexicographic approach (referred to as lexOp).

First the subfields are obtained using exact algorithms which minimize the total beam-

|  |  |  | $d=2$ |  |  |  |  |  |  |  |  | $d=3$ |  |

Table 1: Description of the 62 instances numbered by \#. The columns are $m$ for the number of rows, $n$ for the number of columns, $a_{\max }$ for the maximum intensity level. The number $d$ is the number of subfields, $w$ indicates the subfield width (number of columns), and \#s the number of possible splitting positions.
on time in field splitting with feathering regions. For the unconstraned case, we used the state-of-art algorithm proposed by Kamath et al. [2007] and for the constrained case, due to the lack of an alternative algorithm in the literature, we used the LP model developed in Section 3.1. Then, for each subfield, a single field sequencing algorithm is used to find a decomposition subject to the minimum beam on time of the subfield. We considered two different approaches to find a decomposition of each subfield, namely the sweep technique [Bortfeld et al., 1994] and mixed integer programming.

The sweep technique is computationally efficient and provides a decomposition with minimum beam-on time. However, it might produce a large number of shape matrices. On the other hand, the exact MIP approach requires more computation time but provides a decomposition with the smallest number of shape matrices. In the MIP approach we adapted the $\left(F S D C^{\prime}\right)$ formulation for a single field, by setting $n=w$ and $d=1$, to solve the minimum cardinality problem for each subfield. We refer to the first combination as the "KB" approach and to the latter as the "KMIP" approach in the unconstrained case and as "FSBOTB" and "FSBOTMIP" in the constrained case.

In our implementation of the lexicographic approach if there are multiple sets of subfield positions for the $\left(F S D C^{\prime}\right)$ problem then we used the best decomposition cardinality from previous sets of subfield positions as an upper bound for the subsequent ( $F S D C\left(s^{*}\right)$ ) problems in order to reduce the computational effort. For each mixed integer program we set a time limit of 600 seconds and an upper limit of 6 on number of threads used by CPLEX.

Unconstrained case. Tables 3 and 4 present the results for the unconstrained two and three splitting problem, respectively. Columns labeled "KB" represent results obtained using the field splitting algorithm proposed by Kamath et al. [2007] and the sweep technique, whereas columns labeled "KMIP" represent results obtained using the algorithm of Kamath et al. [2007] followed by MIP.

The "KB" approach was the fastest to produce a decomposition, in less than 1 second for each instance (which is why we omit computation times in Tables 3 and 4 . However, it produced a much larger number of shape matrices in comparison to the "KMIP" approach and our "lexOp" method. Solutions provided by "KMIP"' were on average $52.3 \%$ and $51.3 \%$ better than those provided by the "KB" approach for the two and three splitting problems, respectively.

For the two and three splitting problems, CPLEX was able to solve to optimality 57 (61) instances using the "KMIP" approach and 50 (57) instances using the "lexOp" approach. That is, CPLEX was able to solve more instances exactly using the "KMIP" than the "lexOp" approach and it solved those instances faster. This can be explained by the size and number of MIP problems considered in the two approaches. For example, for three splitting instance 24, "KMIP" requires to solve three ( $F S D C^{\prime}$ ) problems with $d=1$, i.e., one for each subfield of size $10 \times 4$ whereas "lexOp" requires the solution of two ( $F S D C^{\prime}$ ) problems with $d=3$ for the intensity matrix of size $10 \times 10$, one for each candidate set of positions that provides the
minimum beam-on time, see Table 4.
We have to note, however, that the "KMIP" approach did not provide a Pareto optimal solution for $80 \%$ (40 out of 50) respectively $80.7 \%$ (46 out of 57 ) of instances solved to optimality for both the "KMIP" and "lexOp" approaches for the two and three splitting problems, respectively. For those instances, "KMIP" provided on average $9.5 \%$ more shape matrices than "lexOp".

For the two splitting problem, 12 instances were not solved to optimality with the "lexOp" approach within the time limit. However, in 8 out of 12 of those instances, the feasible solutions obtained with the "lexOp" approach were not worse than those obtained with the "KMIP" approach, despite 7 of these instances being solved to optimality for the "KMIP" approach. The remaining 4 instances were not solved to optimality for both approaches and "KMIP" provided better solutions than "lexOp". The indices of these instances (51, 52, 53 and 55) are highlighted in bold in Table 3.

For the three splitting problem, 5 instances were not solved to optimality using the "lexOp" and 1 instance using the "KMIP" approach. However, only for instance 53 did the lexicographic approach provide a feasible decomposition with larger number of shape matrices than "KMIP". On average "lexOp" provided $9 \%$ fewer shape matrices than "KMIP".

Constrained case. The results for the constrained two and three splitting problems are shown in Tables 5 and 6 . We observed the same general behaviour as for the unconstrained version of the problems. The "FSBOTB" was the fastest approach but also the worst in terms of the number of shape matrices produced.

For the two splitting problem, 52 instances were solved to optimality for both the "FSBOTMIP" and "lexOp" approaches. For these instances, "lexOp" produced on average 10.5\% fewer shape matrices than "FSBOTMIP". We also note that "FSBOTMIP" failed to produce a Pareto optimal solution for 44 out of those 52 instances. Of the remaining 10 instances, 4 were solved to optimality and a feasible solution was obtained for 6 using the "FSBOTMIP" approach. Using the "lexOp" approach, CPLEX found feasible solutions for eight instances, but failed to produce a feasible solution for instances 52 and 53 . Comparing the eight instances, the feasible solutions obtained for "lexOp" had a greater number of shape matrices than "FSBOTMIP" for the three instances 49,51 and 55 and a smaller number of shape matrices for the other five, despite four of these five being solved to optimality with the the "FSBOTMIP" approach.

For the three splitting problem, CPLEX was able to produce 60 optimal and 2 feasible solutions using the "FSBOTMIP" approach. Using the "lexOp" approach it produced optimal solutions for 52 and feasible solutions for 9 instances, whereas it failed to produce any feasible solution for instance 53. Comparing the 52 instances which were solved to optimality using both approaches, we observe that the lexicographic approach produced on average $10 \%$ fewer shape matrices. For 41 of the 52 instances, the optimal solution obtained for "FSBOTMIP" was not Pareto optimal. Finally, for seven of the nine instances for which CPLEX only found
a feasible solution using the "lexOp" approach, the number of shape matrices was still smaller than for the optimal solution obatined using the "FSBOT_MIP" approach.

## 5 Conclusion

In this paper we discussed the realization problem in IMRT with objective functions total beam-on time and decomposition cardinality. In particular, we focused on the usage of linear accelerators and multileaf collimators with limited width (maximum leaf spread constraint) which led us to the investigation of field splitting with feathering. We addressed unconstrained and constrained (interleaf collision constraint) versions of the problem and developed a new approach to determine the minimum beam-on time for both these cases. Furthermore, we proved the decomposition cardinality problem with field splitting to be $\mathcal{N} \mathcal{P}$-hard even for a single row intensity matrix and without feathering. We then introduced a lexicographic approach that minimizes the decomposition cardinality subject to minimum beam-on time. The approaches presented in this article use integer programming formulations that we implemented to obtain numerical results for clinical as well as randomly generated instances. We compared our new lexicographic approach with other approaches which first solve the beam-on-time problem with field splitting and then apply either a heuristic or exact algorithm to minimize the number of shape matrices in the decomposition of the subfields. The results show that using the sweep-technique as a heuristic is very fast, but far inferior in terms of number of shape matrices. Our lexicographic approach clearly results in the lowest number of shape matrices, but may not find an optimal (or even feasible) solution in some cases if computation time is limited. Even then, feasible solutions found are often better than optimal solutions found by the sequential approach. We note that the few instances in which the lexicographic approach did not find any feasible solutions were among the instances with the largest number of rows.

In future work we intend to address the problems discussed in this paper by means of heuristics. This alternative approach will help to produce at least feasible solutions for those instances of $(F S D C)$ for which the exact methods presented here failed to produce such solutions within the fixed time limit.

## Acknowledgments

The authors would like to thank Prof. Srijit Kamath for providing the code for unconstrained field splitting with feathering region.

This work is partially supported by the Australian Government, Department of Innovation, Industry, Science and Research, Collaborative Research Networks Program (grant CRN2011:07) and grants no. 13N13198 and 13N14561 of the German Ministry of Research and Technology (BMBF). In addition, we would like to acknowledge the support from the European Union Seventh Framework Programme (FP7-PEOPLE-2009-IRSES) under Grant agreement 246647 and the support from the New Zealand Government (Grant no. 649378v2) as part of the Optimization and its Applications in Learning and Industry project.
