## ABSTRACT

We present Keck spectroscopic observations and redshifts for a sample of 767 *Herschel*<sup>1</sup>-SPIRE selected galaxies (HSGs) at 250, 350, and 500  $\mu\text{m}$ , taken with the Keck I Low Resolution Imaging Spectrometer (LRIS) and the Keck II DEep Imaging Multi-Object Spectrograph (DEIMOS). The redshift distribution of these SPIRE sources from the *Herschel* Multitiered Extragalactic Survey (HERMES) peaks at  $z = 0.85$ , with 731 sources at  $z < 2$  and a tail of sources out to  $z \sim 5$ . We measure more significant disagreement between photometric and spectroscopic redshifts ( $\langle \Delta z / (1 + z_{\text{spec}}) \rangle = 0.29$ ) than is seen in non-infrared selected samples, likely due to enhanced star formation rates and dust obscuration in infrared-selected galaxies. The infrared data are used to directly measure integrated infrared luminosities and dust temperatures independent of radio or 24  $\mu\text{m}$  flux densities. By probing the dust spectral energy distribution (SED) at its peak, we estimate that the vast majority (72–83%) of  $z < 2$  *Herschel*-selected galaxies would drop out of traditional submillimeter surveys at 0.85–1 mm. We find that dust temperature traces infrared luminosity, due in part to the SPIRE wavelength selection biases, and partially from physical effects. As a result, we measure no significant trend in SPIRE color with redshift; if dust temperature were independent of luminosity or redshift, a trend in SPIRE color would be expected. Composite infrared SEDs are constructed as a function of infrared luminosity, showing the increase in dust temperature with luminosity, and subtle change in near-infrared and mid-infrared spectral properties. Moderate evolution in the far-infrared (FIR)/radio correlation is measured for this partially radio-selected sample, with  $q_{\text{IR}} \propto (1 + z)^{-0.30 \pm 0.02}$  at  $z < 2$ . We estimate the luminosity function and implied star-formation rate density contribution of HSGs at  $z < 1.6$  and find overall agreement with work based on 24  $\mu\text{m}$  extrapolations of the LIRG, ULIRG and total infrared contributions. This work significantly increased the number of spectroscopically confirmed infrared-luminous galaxies at  $z \gg 0$  and demonstrates the growing importance of dusty starbursts for galaxy evolution studies and the build-up of stellar mass throughout cosmic time.

## 1. INTRODUCTION

Ultraluminous Infrared Galaxies (ULIRGs;  $L_{\text{IR}} > 10^{12} L_{\odot}$ ) exhibit the most extreme star-formation rates in the Universe (see an overview in Lonsdale, Farrah & Smith 2006). At early epochs ( $z > 1$ ), ULIRG activity contributes significantly to the build-up of stellar mass presumably through intense star-forming bursts (with  $\tau \lesssim 100$  Myr and  $\text{SFR} \gtrsim 500 M_{\odot} \text{ yr}^{-1}$ , e.g. see Sanders & Mirabel 1996; Blain *et al.* 2002; Smail *et al.* 2002). Since the observed properties of these starbursts are short-lived and intense, they are thought to be triggered by the collision of gas-rich disk galaxies (Engel *et al.* 2010) and serve as a fundamental transition phase to luminous active galactic nuclei (AGN) or quasars (Sanders *et al.* 1988). Although the merger history of high- $z$  ULIRGs has recently come into question, with some evidence pointing to a substantial (perhaps  $> 50\%$ ) fraction of ULIRGs building stellar mass through minor mergers or passive gas accretion (Daddi *et al.* 2010; Elbaz *et al.* 2011; Rodighiero *et al.* 2011), there is little doubt that ULIRGs contribute non-negligibly to the star formation history of the Universe and the formation of massive elliptical galaxies at the present day (e.g. Kartaltepe *et al.* 2010). Unfortunately, much about the infrared starburst population<sup>28</sup> is still unknown due to limitations in far-infrared (FIR) observations, strong selection biases and sample inhomogeneity.

Galaxies which have been called ‘Submillimetre Galaxies’ (SMGs), are selected at wavelengths around 1 mm, particularly in the atmospheric window at  $850 \mu\text{m}$ . Such ‘classical SMGs’ with  $S_{850} \gtrsim 5 \text{ mJy}$  (Smail *et al.* 2002) have put powerful constraints on galaxy evolution theories and the environments of heavy star formation since their initial discovery a decade ago (Smail, Ivison & Blain 1997; Hughes *et al.* 1998; Barger *et al.* 1999). However, their selection at wavelengths  $850 \mu\text{m}$ – $1.4 \text{ mm}$  is susceptible to strong temperature biasing (Blain *et al.* 2004; Chapman *et al.* 2004; Casey *et al.* 2009; Chapman *et al.* 2010; Magdis *et al.* 2010). This leaves the possibility that a significant fraction of high- $z$  ULIRGs have yet to be discovered and characterised. Building a comprehensive sample of spectroscopically-confirmed submillimetre galaxies or extreme starbursts is paramount for determining the evolutionary histories of ULIRGs by breaking the  $T_{\text{dust}}/(1+z)$  degeneracy, for carrying out stellar population analysis, and for measuring the AGN stage and contribution to luminosity.

The *Herschel Space Observatory* (Pilbratt *et al.* 2010) has identified thousands of galaxies at  $70$ – $500 \mu\text{m}$ , wavelengths previously near-inaccessible from the ground, sampling galaxies’ emission at the peak of their SEDs at  $z \sim 2$ , when the importance of dusty starbursts in the global context of the Universe’s star formation is most evident (Chapman *et al.* 2005). The SPIRE instrument (Griffin *et al.* 2010) will map  $\sim 350 \text{ deg}^2$  in sky near the

confusion limit at  $250$ ,  $350$  and  $500 \mu\text{m}$  as part of the *Herschel* Multi-tiered Extragalactic Survey (HerMES; Oliver *et al.* in press), covering areas much larger than SCUBA, MAMBO, AzTEC or LABOCA. With much larger areas, the rarest sources can be uncovered and the dynamic range of sources thereby expands, from nearby luminous infrared galaxies (LIRGs;  $> 10^{11} L_{\odot}$ ) to distant hyper-luminous infrared galaxies (HyLIRGs;  $> 10^{13} L_{\odot}$ ) and lensed sources. Working towards completeness in high redshift starburst samples, and removing the impact of selection biases introduced by prior starburst selection techniques, is a key long term goal.

Understanding ULIRG completeness and, in turn, constraining key astrophysical quantities of the luminous starburst population, is only possible with a spectroscopic census of a diverse population of FIR-luminous galaxies. Redshift identification is a crucial piece of information for a high-redshift dusty galaxy, since it allows the measurement of its luminosity and star-formation rate, and is a prelude to subsequent interferometry (often dependent on a known redshift) in order to constrain the vast reservoirs of molecular gas which fuel extreme starbursts. Such subsequent studies cannot be completed using photometric data alone, and to date, Keck LRIS and DEIMOS multi-slit spectroscopy is the most efficient method for uncovering large samples of galaxy redshifts, for both normal star-forming  $z > 1$  galaxies (Cowie & Hu 1998; Cowie, Songaila & Barger 1999; Cowie *et al.* 2001; Steidel *et al.* 1996, 1999) and heavily dust-obscured ULIRGs (Barger *et al.* 1998, 1999; Barger, Cowie & Richards 2000; Cowie, Barger & Kneib 2002; Chapman *et al.* 2005).

This paper presents the first results from a large spectroscopic redshift survey of 1594 *Herschel*-SPIRE selected galaxies (HSGs). We measure redshifts for 767 of 1594 targeted HSGs, describe their bulk infrared properties, address their relationship to the now well-studied SMGs, and assess their contribution to cosmic star formation. The results of this spectroscopic survey have been split into two papers of which this is the first, presenting the details of source selection, completeness, spectroscopic confirmations and associated results for  $z < 2$  sources. An accompanying paper presents the  $2 < z < 5$  sub-sample in more detail. Throughout we use a flat  $\Lambda$ CDM cosmology (Hinshaw *et al.* 2009) with  $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$  and  $\Omega_{\text{M}} = 0.27$ .

## 2. HERSCHEL-SELECTED GALAXY SAMPLE

The sources observed in this paper were detected by the *Herschel Space Observatory* SPIRE instrument as part of the *Herschel* Multi-tiered Extragalactic Survey (HerMES; Oliver *et al.* in prep.). SPIRE, the Spectral and Photometric Imaging Receiver (Griffin *et al.* 2010), is designed for wide-field mapping at  $250$ ,  $350$ , and  $500 \mu\text{m}$ . The beamsizes at these respective wavelengths are  $18''$ ,  $25''$ , and  $36''$  with measured mean point-source confusion noise uncertainties of  $\sigma_{250} = 3.8 \text{ mJy}$ ,  $\sigma_{350} = 4.6 \text{ mJy}$ , and  $\sigma_{500} = 5.2 \text{ mJy}$  which dominates over instrumental noise (these values are for  $3\sigma_{\text{conf}}$  cuts used for de-boosted photometric measurements, see the SPIRE Observers’ Manual and Griffin *et al.* 2010; Nguyen *et al.* 2010). We make use of SPIRE maps as described by Levenson *et al.* (2010).

In this paper, deep ancillary data, particularly radio

NSW 1710, Australia

<sup>1</sup> *Herschel* is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA.

<sup>28</sup> In this paper, we use the term ‘starburst’ to refer to high-SFR galaxies ( $\text{SFR} > 100 M_{\odot} \text{ yr}^{-1}$ ). This differs from the recent definition of ‘starburst’ as a combination of SFR and stellar mass (e.g. Noeske *et al.* 2007; Rodighiero *et al.* 2011).

and  $24\mu\text{m}$ , are essential for optical spectroscopic surveying. We observe sources in the Lockman Hole North (LHN) whose *Spitzer* imaging comes from the *Spitzer* Wide-Area Infrared Extragalactic (SWIRE) survey (Lonsdale *et al.* 2003) and GO MIPS programs (PI Owen) and very deep 1.4 GHz mapping from the Very Large Array (VLA) (Owen & Morrison 2008). LHN has additional coverage with *Herschel*-PACS from HerMES (PI G. Magdis). In the Great Observatories Origins Deep Survey North (GOODS-N) field, deep 1.4 GHz radio mapping comes from the VLA (Morrison *et al.* 2010) and *Spitzer* coverage of the GOODS-N center is from FIDEL (Dickinson *et al.* in prep.) and some of the extended area is from *Spitzer* program ID83 (PI Rieke; Shupe, private communication). We also observe sources in the ELAIS-N1 (EN1) and extended UKIDSS Ultra Deep Field (UDS)/XMM fields, both extragalactic areas in the SWIRE survey. The UDS has additional coverage from the *Spitzer* Legacy Program (SpUDS; PI Dunlop). Radio coverage of the EN1 field is substantially more sparse than in GOODS-N or LHN, with the only mapping taken with the GMRT at 610 MHz (Garn & Alexander 2008) and 325 MHz (Sirothia *et al.* 2009), whose depths effectively translate to  $100\mu\text{Jy}$  RMS at 1.4 GHz assuming a synchrotron slope of  $\alpha=0.75$ , where  $S \propto \nu^{-\alpha}$  (e.g. Dale *et al.* 2007). Our UDS observations sit on the edge of a new deep VLA radio map with  $\sim 7\mu\text{Jy}$  RMS (Arumugam *et al.* in prep.). In the Cosmic Evolution Survey field (COSMOS; Scoville *et al.* 2007), radio coverage in the central  $1\text{ deg}^2$  has a depth of  $\sim 10.5\mu\text{Jy}$  RMS (Schinnerer *et al.* 2007) and *Spitzer* coverage is described in Sanders *et al.* (2007), Le Floch *et al.* (2009) and Frayer *et al.* (2009). COSMOS is also covered by PACS as part of the PEP program (PI D. Lutz). We additionally observed sources in the Extended Chandra Deep Field South or ECDF-S region which has deep radio coverage (Miller *et al.* 2008; Biggs *et al.* 2011), as well as *Spitzer*-MIPS  $24\mu\text{m}$  from FIDEL and IRAC (Damen *et al.* 2011).

We use the photometric redshift catalogs from SWIRE (EN1) described by Rowan-Robinson *et al.* (2008), the deep LHN catalog in Strazzullo *et al.* (2010), and the extensive COSMOS (Ilbert *et al.* 2010) and ECDFS (Cardamone *et al.* 2010) catalogs. In GOODS-N, since we survey radio galaxies outside of the central deep region, the photometric catalog is limited, so we exclude it from photometric redshift analysis.

### 2.1. Source Extraction and Photometry

SPIRE point source photometry is performed by flux extraction at positions of known  $24\mu\text{m}$  sources or radio 1.4 GHz sources. This cross-identification prior source extraction (XID) method is described in detail in Roseboom *et al.* (2010) with some follow-up discussion in Roseboom *et al.* (2012). The disadvantage of the XID technique is that it excludes any sources which are not  $24\mu\text{m}$  or radio identified. This is particularly problematic for potentially high-redshift sources which drop out of both  $24\mu\text{m}$  and radio surveys, and might have ambiguous near-IR counterparts; since  $24\mu\text{m}$  and radio source dropouts are excluded from this sample, and their influence is undoubtedly more significant at high-redshifts than at  $z < 2$  (e.g. Magdis *et al.* 2011; Béthermin *et al.* 2012), the high- $z$  sample is treated in a separate paper (Casey *et al.* 2012, henceforth C12).

The advantage of cross-identification with  $24\mu\text{m}$ /IRAC and radio sources is that it can correct for confusion boosting in the extracted SPIRE flux densities by estimating the flux contributions from nearby sources within one beamsize. It also reduces the confusion noise by a factor of  $\sim 2$  by pushing slightly below the nominal confusion limit using the Least Absolute Shrinkage and Selection Operator (LASSO) method to assign SPIRE flux densities to an overdense prior source list (see Roseboom *et al.* 2010, for method details). The LASSO algorithm combines strengths of model prediction and filter prediction source identification (i.e. balancing source priors to the SPIRE map flux distribution with choosing the brightest source correspondence between  $24\mu\text{m}$ /radio and SPIRE). The algorithm upweights ‘rare’ sources, therefore radio sources are preferred SPIRE counterparts over  $24\mu\text{m}$  sources. This makes sense given the expectation that radio sources are FIR-luminous (Helou, Soifer & Rowan-Robinson 1985; Condon 1992). The procedure assumes that the ancillary data are of adequate depth to identify the vast majority of FIR emitting sources, so it is only practical in deep legacy survey fields.

### 2.2. Completeness of Source Catalog

The most crucial aspect of a redshift survey is having a clear understanding of survey completeness and biases. This subsection addresses our survey’s completeness in identifying strong SPIRE sources using the XID flux extraction method.

Since this is a test of the robustness of the XID technique, the results will vary by field (LHN, GOODS-N, EN1, COSMOS, CDFS and UDS), based on survey depths, and is a function of SPIRE flux density. Roseboom *et al.* (2010) demonstrate that the robustness of the XID catalog depends greatly on the depth of ancillary data available in the field to act as source priors. Beyond a fairly standard depth at  $24\mu\text{m}$  of  $S_{24} \sim 150\mu\text{Jy}$  (or a sky density of  $\gtrsim 3000\text{ deg}^{-2}$ ), XID source flux extraction will be  $>95\%$  complete at the  $3\sigma$  limit of SPIRE (where  $\sigma$  includes instrumental and confusion noise, and  $3\sigma$  roughly corresponds to a  $\gtrsim 15\text{ mJy}$  cut-off). At higher source densities XID is more robust, even when the source density of priors exceeds the number of SPIRE-bright sources.

The completeness of the XID process is tested by first producing residual maps at the SPIRE wavelengths using the best fit XID solution, and then re-injecting sources into these maps using a number count and clustering model consistent with the real data. The XID process is repeated on these simulated images and the results are assessed to determine the number of sources returned at  $> 3\sigma$  as a function of injected flux density. This process is repeated several times for different realisations of the SPIRE maps to build up suitable statistics across a wide range of SPIRE flux densities. The results of this process are shown in Figure 1 for the field with the shallowest ancillary data, EN1; deeper fields have completeness curves approaching boxcar functions. This completeness curve is generated using the same analysis from Roseboom *et al.* (2010) with improvements described in Roseboom *et al.* (2012). An  $S_{\text{SPIRE}} > 15\text{ mJy}$  limit should be  $>80\%$  complete at  $500\mu\text{m}$  ( $>95\%$  for  $250\mu\text{m}$  and  $350\mu\text{m}$ ), and

FIG. 1.— XID catalog completeness curves in the EN1 field as a function of flux density at SPIRE wavelengths  $250\,\mu\text{m}$  (blue),  $350\,\mu\text{m}$  (green) and  $500\,\mu\text{m}$  (red). The dotted vertical lines mark the  $3\sigma$  noise limits at the respective wavelengths. This completeness measure is a reflection of the XID catalog’s ability to assign and identify  $24\,\mu\text{m}$  or radio counterparts for all SPIRE sources at a given flux density.

a  $20\,\text{mJy}$  limit should be  $>95\%$  complete in all fields. Additional sources are identified down to flux densities comparable to the confusion limits ( $5\text{--}6\,\text{mJy}$ ). This is below the nominal  $3\sigma$  cut-off and is achieved by using positional priors of many galaxies thought only to emit at SPIRE wavelengths at levels  $\sim 0.1\text{--}1\,\text{mJy}$ ; the flux density of SPIRE-bright sources is then ‘deboosted’ using the density of source priors which are thought to be SPIRE-faint.

Note that the ability to match counterparts down to  $15\,\text{mJy}$  does not necessarily mean that counterpart matching is always correct (an issue which is so far largely unconstrained, but is starting to be addressed through systematic interferometric work, e.g. Wang *et al.* 2011). This question, particularly as it applies to the application of the XID extraction technique, is discussed in Roseboom *et al.* (2010).

### 2.3. Completeness in Radio, $24\,\mu\text{m}$ Samples

The source density of  $>3\sigma$  SPIRE-significant XID sources is constant within a factor of  $\sim 2$  ( $1500\text{--}3000\,\text{deg}^{-2}$ ) despite large variations in ancillary data across the different fields. For example, the Lockman Hole North – a field with ultra-deep radio coverage and deep *Spitzer* mid-infrared coverage – has a source density of  $\sim 3000\,\text{deg}^{-2}$  for sources above  $S_{1.4} \sim 25\,\mu\text{Jy}$  or  $S_{24} \sim 150\,\mu\text{Jy}$ , which is the same density measured in ELAIS-N1 – a field with only very shallow radio coverage – and in the GOODS-N flanking fields – an area not completely covered by *Spitzer*. Figure 2 shows the cumulative surface densities of sources selected at  $24\,\mu\text{m}$  and radio, then selected to be  $>3\sigma$  in at least one of the SPIRE bands. The surface density of  $24\,\mu\text{m}$  SPIRE-significant sources is about a factor of 2 times the surface density of radio SPIRE-significant sources, assuming a rough correlation between  $24\,\mu\text{m}$  and  $1.4\,\text{GHz}$  radio flux density of  $S_{24} \approx 3.7 S_{1.4}$  (which we measure from Figure 3). Figure 2 also highlights that the surface density of any one field is dependent on the depth of the prior catalog, although across all fields this is consistent within a factor of about 2. With comparable surface densities  $\sim 1500\text{--}3000\,\text{deg}^{-2}$ , one might then ask whether this means that  $24\,\mu\text{m}$  identified sources in EN1/COSMOS/CDFS/UDS and the radio-identified ( $>40\,\mu\text{Jy}$ ) sources in LHN/GOODS-N/COSMOS/CDFS

are drawn from the same population of IR galaxies.

Figure 3 investigates the relation between  $24\,\mu\text{m}$  and  $1.4\,\text{GHz}$  flux density for the LHN subsample which contains the deepest ancillary data. Our SPIRE targets are shown against normal field galaxies, both carving out a similar parameter space, indicating no clear SPIRE-bright/faint bias. Using our LHN sample as a guide, we find that  $70 \pm 20\%$  of  $S_{1.4} \geq 40\,\mu\text{Jy}$  sources have  $S_{24} \geq 150\,\mu\text{Jy}$  (see Fig 4), suggesting that most sub-mJy radio sources are sub-mJy  $24\,\mu\text{m}$  sources. This highlights that: (a) the incidence of SPIRE-detection is higher in faint radio sources than in  $24\,\mu\text{m}$  sources; and (b) that nearly all radio sources ( $\sim 70\%$ ) are  $24\,\mu\text{m}$  detected and a large fraction of  $24\,\mu\text{m}$  sources are radio detected (from Fig 4). Since our sample is rest-frame FIR selected and is likely to obey the FIR/radio correlation (Helou, Soifer & Rowan-Robinson 1985), our sources are more likely to be radio-detected than random field galaxies. Also, given the beamsize of *Herschel* to be  $18\text{--}36''$ , the probability of random coincidence with a radio galaxy is  $>8$  times lower than with a  $24\,\mu\text{m}$  galaxy, thus the probability of correct counterpart identification is  $>8$  times higher in radio galaxies than it is in  $24\,\mu\text{m}$  galaxies (although that probability itself cannot be constrained without interferometric infrared observations).

The typical range of surface densities of SPIRE galaxies,  $\sim 1500\text{--}3000\,\text{deg}^{-2}$ , translates to an expected number of SPIRE-detected sources per slit-mask of  $N_{\text{DEIMOS}} = 33^{+15}_{-8}$  sources per mask and  $N_{\text{LRIS}} = 17^{+8}_{-4}$  sources per mask across all fields (derived from mean and standard deviations of source densities between the six survey fields). This agrees with our actual spectroscopic sampling per slit-mask; we average  $33 \pm 7$  significant SPIRE-sources per DEIMOS slit-mask and  $20 \pm 6$  sources per LRIS slit-mask.

It is important to note that this analysis only tests the completeness and source density for galaxies already detected at mid-infrared or radio wavelengths. Some sources will be excluded from the XID catalog since they will not be detected in the ancillary data. Important examples are very high redshift sources which are radio-faint and  $24\,\mu\text{m}$ -faint and cannot be identified due to a lack of a multi-wavelength counterpart(s). These high-redshift sources will have a profound effect on the derived IR luminosity function at  $z > 3$ ; therefore, this is a significant limitation of this HSG sample. However, at lower redshift we suspect that, at the least, the XID catalog is  $80\%$  complete out to  $z = 2$  (again, see more details on estimated completeness as a function of redshift in Roseboom *et al.* 2010). The completeness of the XID catalog with respect to the low redshift sources,  $z \lesssim 2$ , has also been shown to be  $\approx 95\%$  (Magdis *et al.* 2011).

### 2.4. Spectroscopic Target Characteristics

Slit-masks for the Keck Low Resolution Imaging Spectrometer (LRIS; Oke *et al.* 1995) and DEep Imaging Multi-Object Spectrograph (DEIMOS; Faber *et al.* 2003) were populated by a prioritization scheme, whereby sources were graded in priority from 0 to 1000 by their SPIRE photometry, radio detection or non-detection, and  $24\,\mu\text{m}$  flux density. No optical magnitude selection or prioritization was made. Note that there was no filtering of the sample to remove low redshift targets or quasars (as was often done for SMGs, e.g. Chapman *et*

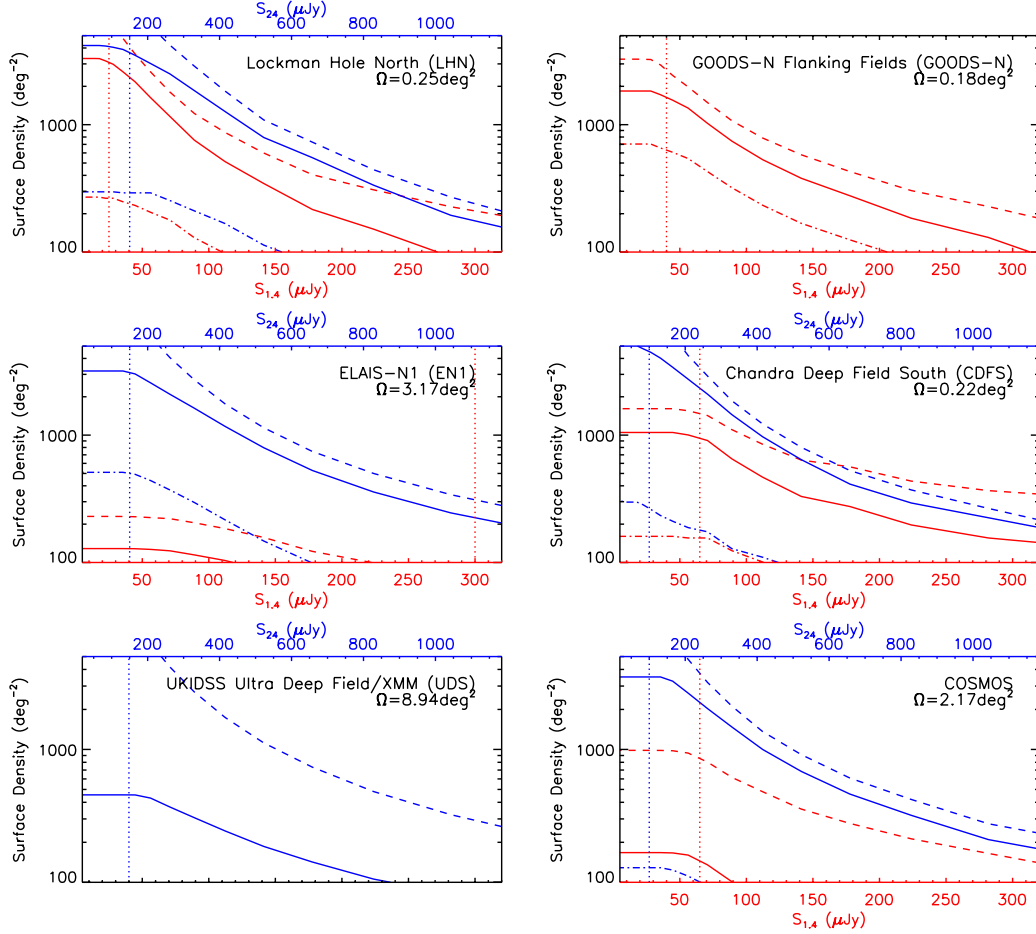

FIG. 2.— Cumulative surface density of  $24\mu\text{m}$  and radio sources with flux density. In other words, as a function of radio *or*  $24\mu\text{m}$  flux density, we plot the surface density of sources with flux densities above that given flux density. Dashed lines represent the parent population of all  $24\mu\text{m}$  sources (*blue*) and radio sources (*red*) in the whole field. Each panel is labeled at top with a  $24\mu\text{m}$  flux density scale and at bottom with a  $1.4\text{GHz}$  flux density scale (the scales are omitted if the data are insufficient/do not exist). Solid lines represent the source density for sources which are  $>3\sigma$  significant in at least one of the three SPIRE bands. Dot-dashed lines represent sources  $>3\sigma$  significant in all three SPIRE bands. Vertical dotted lines mark where  $24\mu\text{m}$  or radio catalogs become incomplete in flux density.

*al.* 2005). The *i*-band magnitudes of our spectroscopic targets are plotted against the brightest SPIRE flux in Figure 5. Since our spectroscopic sampling is exclusively driven by SPIRE detectability and not by optical magnitude, there is no clear relationship perceived in Figure 5. When there was no *i*-band or *z*-band counterpart to center our slit on, we used the IRAC  $3.6\mu\text{m}$  position or radio VLA position, which are both good to  $\sim 0.7''$  given their relatively small beamsizes.

Sources detected at  $>3\sigma$  in at least one out of the three SPIRE bands were given a priority = 300, and sources detected in all three SPIRE bands at  $>3\sigma$  were given a priority = 500. Mask centers and orientations were chosen based on the positions of rare, ‘red’  $500\mu\text{m}$ -peaking sources ( $S_{250} < S_{350} < S_{500}$ ), thought to be the highest-redshift SPIRE-bright galaxies (Cox *et al.* 2011). These red sources were given very high priority,  $>800$ , and if their multi-wavelength properties were consistent with a high-*z* source, e.g.  $i_{\text{AB}} > 22$  and  $S_{24} < 500\mu\text{Jy}$ , priority was graded even higher, at 1000. The prioritization scheme is linear, such that a source with priority 1000 will be assigned a slit in favor of two  $p=300$  sources, or one  $p=300$  source plus one  $p=500$  source, however, a  $p=800$  source would be passed up in lieu of two  $p=500$  sources. While this scheme could accidentally remove

very high priority sources from our masks, we adjusted mask position angles manually to ensure optimal spatial sampling, and were only minimally affected by source overlap ( $\lesssim 5\%$  of slits were conflicted).

The density of our sources, both low and high priority, is high enough and comparatively uniform over the LHN, GOODS-N, EN1, UDS, CDFS and COSMOS fields such that our mask coverages constitute a random sampling, and completeness estimates are performed with respect to the sky area probed by the masks alone (which total  $\sim 0.93\text{deg}^2$ ). Note that the centering of our masks around high-priority ‘red’ sources might give a high-redshift bias to our sample, since we set out to find some of the rarest, high-*z* HyLIRGs. What we find (to be discussed later in the paper and more in C12) is that the redshift distribution of ‘red’ targets is *not* strongly biased towards high-*z*. There are actually more high-*z* sources which are not red than are, leading us to believe that the sky sampling is essentially random, despite our efforts to detect more high-*z* galaxies. The density of  $>3\sigma$  SPIRE sources is also low enough so that our radio,  $24\mu\text{m}$  or SPIRE color prioritization does not introduce statistically significant selection biases into the sample; in other words, nearly all ( $>90\%$ ) the  $>3\sigma$  SPIRE sources within areas covered by slit-masks were spectroscopically

FIG. 3.— The distribution of LHN targets in 1.4 GHz radio flux density ( $S_{1.4}$ ) versus  $24\mu\text{m}$  flux density ( $S_{24}$ ). The various flux limits in the three different fields are marked. Black points represent field galaxies while red points denote SPIRE-selected galaxies. Note that SPIRE detection is largely uncorrelated with  $24\mu\text{m}$  or radio flux density. However, faint  $24\mu\text{m}$  sources tend also to be faint in the radio (roughly corresponding to  $S_{24} \sim 3.7 \times S_{1.4}$  as measured here), leading us to conclude that the majority of faint  $24\mu\text{m}$  EN1 sources are drawn from the same population as the GOODS-N radio sources (also see the work of Magdis *et al.* 2011).

FIG. 4.— The fraction of radio sources (red) or  $24\mu\text{m}$  sources (blue) which are SPIRE-detected as a function of radio or  $24\mu\text{m}$  flux density. The ‘x’s represent the fraction of  $24\mu\text{m}$  SPIRE sources which are also radio-detected (blue) and radio SPIRE sources which are also  $24\mu\text{m}$ -detected. Here we use  $S_{24} \sim 3.7 \times S_{1.4}$ , which is the rough relation we observe for field galaxies in Figure 3; this scaling allows us to judge the relative depths of the catalogs. ‘Depth A’ corresponds roughly to  $S_{1.4} \sim 40\mu\text{Jy}$  and  $S_{24} \sim 150\mu\text{Jy}$ , ‘Depth B’ corresponds roughly to  $S_{1.4} \sim 25\mu\text{Jy}$  and  $S_{24} \sim 100\mu\text{Jy}$ , and ‘Depth C’ corresponds roughly to  $S_{1.4} \sim 15\mu\text{Jy}$  and  $S_{24} \sim 70\mu\text{Jy}$ . ‘Depth A’ corresponds to the EN1 and UDS  $24\mu\text{m}$  limit, ‘Depth B’ corresponds to LHN  $24\mu\text{m}$  and COSMOS/GOODS-N/CDFS radio limits, while ‘Depth C’ corresponds to the LHN radio limit and GOODS-N(center)/CDFS  $24\mu\text{m}$  limit.

observed.

We assigned slits for 100% of the very high priority ‘red’ targets, 95% of the high priority targets ( $>500$ ), and 90% of the lower priority targets ( $300 < p < 500$ ), filling any free space with additional objects not discussed in this paper (radio sources or  $24\mu\text{m}$  galaxies with insignificant SPIRE fluxes). Any high-priority SPIRE sources not

FIG. 5.— Optical  $i$ -band magnitude (AB) against SPIRE flux density (the brightest flux density is taken from SPIRE  $250\mu\text{m}$ ,  $350\mu\text{m}$  or  $500\mu\text{m}$ ) for sources in EN1 (similar results for other fields). Black points are all significant SPIRE sources used to fill our slitmasks. The selection of these SPIRE sources is not a function of optical magnitude.

observed were only excluded on the basis of the mask configuration, where observing them would bump another high-priority source off a slit. However, the exclusion of high-priority SPIRE sources is rare enough that having a few missing from our sample does not impact our completeness, particularly since we find no significant bias towards high-redshift spectroscopic identifications in the high-priority target sub-sample (see C12 for more details on the  $z > 2$  sub-sample).

Our targets’ distribution in radio flux density and in  $24\mu\text{m}$  flux density and SPIRE signal-to-noise is shown in Figure 6. Out of 1594 targets, 633 are 1.4 GHz identified, 1319 are  $24\mu\text{m}$  identified, and 588 are both radio and  $24\mu\text{m}$  identified. The sources which are selected in both radio and  $24\mu\text{m}$  maps come primarily from the LHN, COSMOS or CDFS fields, since EN1 and UDS lacks deep radio coverage and many sources in the flanking fields of GOODS-N lack deep *Spitzer*  $24\mu\text{m}$  coverage.

Throughout this paper, we refer to our sample as *Her-schel* SPIRE-selected galaxies (HSGs). We prefer not to call them submillimetre galaxies (SMGs) for sake of confusion with the historical definition of SMG selected at  $850\mu\text{m}$ – $1.4\text{mm}$ . We also choose not to use the term ULIRG for our sources since it places the special qualification of a luminosity cut on the sample ( $10^{12} L_{\odot} < L < 10^{13} L_{\odot}$ ). For the rest of the paper, any reference to SMGs refers to a population selected at  $850\mu\text{m}$  with  $S_{850} \geq 5\text{mJy}$ . We use this strict definition of the SMG population in order to draw comparisons between ‘classic SMGs’ and HSGs.

### 3. SPECTRAL OBSERVATIONS AND REDSHIFT IDENTIFICATION

Optical spectroscopic observations were carried out at the W.M. Keck Observatory using LRIS on Keck I and DEIMOS on Keck II in 2011 and 2012.

LRIS observations were carried out in adequate conditions on 2011-Feb-06 with  $\sim 1''$  seeing and cloud cover, on 2012-Jan-26 and 2012-Jan-27 with  $\sim 0.8$ – $1.2''$  seeing with

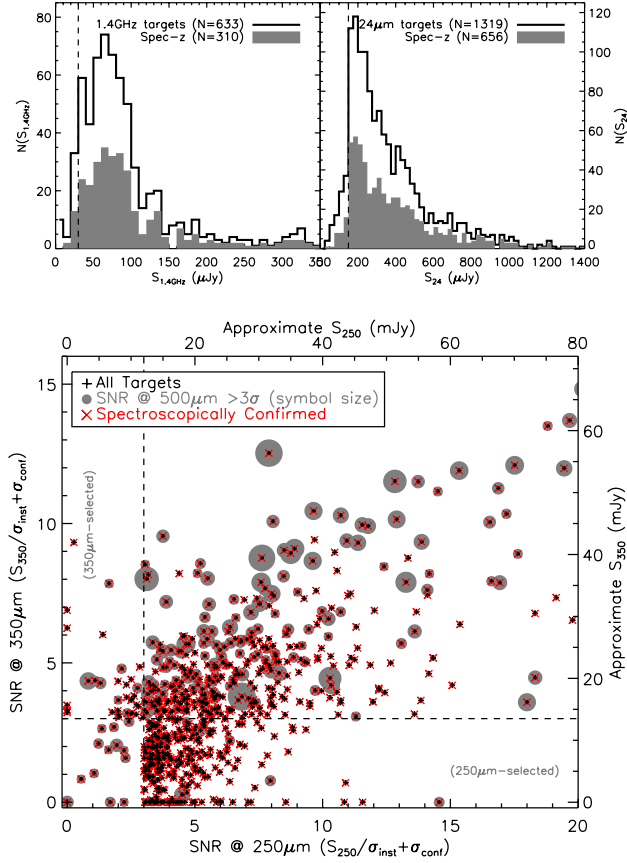

FIG. 6.— **Top:** Distribution of 24  $\mu\text{m}$  and 1.4 GHz radio flux density of our targets. Of our sample, 1319 were primarily identified through 24  $\mu\text{m}$  emission and 633 of were radio selected. The gray distributions reflect the sources with confirmed spectroscopic redshifts (this number exceeds 767 since some sources are identified as both 24  $\mu\text{m}$  and radio sources). The spectroscopic success rates for both samples is  $\sim 55\text{--}60\%$  and does not correlate with flux density. Dashed vertical lines represent average flux density limits of the radio data ( $\sim 30 \mu\text{Jy}$ ) and the 24  $\mu\text{m}$  data ( $\sim 150 \mu\text{Jy}$ ) in our fields. **Bottom:** Each target in our survey must be detected at  $>3\sigma$  in at least one of the three SPIRE bands at 250, 350, or 500  $\mu\text{m}$ . Here we show the 250  $\mu\text{m}$  signal-to-noise ratio (SNR) against 350  $\mu\text{m}$  SNR. The 500  $\mu\text{m}$  SNR scales with the size of the gray circles; if a target is under  $3\sigma$  at 500  $\mu\text{m}$ , it has no gray circle. Spectroscopically confirmed sources are then marked with red crosses, showing no obvious correspondence between FIR flux density and spectroscopic success rates.

minor to no cloud cover, and on 2012-Feb-27 with  $\sim 0.5\text{--}1.0''$  seeing and no cloud cover. We used the 400/3400 grism for maximum wavelength coverage in the blue. The 2011 observations used the 600/7500 grating in the red with a central ‘multi-slit’ wavelength of 6500  $\text{\AA}$ ; the 2012-Jan observations used the 400/8500 grating in the red with a central wavelength of 8400  $\text{\AA}$ , and the 2012-Feb observations used a central wavelength of 8000  $\text{\AA}$ . All observations used clear filters for both red and blue arms and the 560 nm dichroic. These setups give a 1.09  $\text{\AA}$  dispersion in the blue (e.g. shortward of 5600  $\text{\AA}$ ) and a 0.80  $\text{\AA}$  dispersion in the red. Wavelength coverage for each source varied by its position on the  $5.5' \times 7.8'$  slit-mask, the mean wavelength coverage ranged from 2500–8200  $\text{\AA}$  in 2011 and from 2500  $\text{\AA}$ –1  $\mu\text{m}$  in 2012 but varied up to  $\sim 1300 \text{\AA}$  for sources on each mask. Due to the dichroic, some sources near the edge of the slit-mask have gaps in wavelength coverage  $\sim 800 \text{\AA}$  wide in the vicinity

of 5600  $\text{\AA}$ .

We observed a total of 25 LRIS multi-slit masks, 13 of which were observed in near-photometric conditions. LRIS data reduction, including bias subtraction, flat fielding, wavelength calibration, and sky subtraction were all performed using custom-built IDL routines. Of 664 LRIS targets with  $>3\sigma$  SPIRE detections, 268 were spectroscopically identified. 198 of the identified sources (74%) were confirmed in near-ideal conditions; we add asterisks to the NAME column of Table 2 to distinguish these sources from sources confirmed in poorer weather.

DEIMOS observations were carried out in good conditions on 2011-May-28 and 2011-May-29 with  $\sim 0.6\text{--}0.7''$  seeing, on 2011-Nov-28 in average to cloudy conditions with  $\sim 1.0\text{--}1.3''$  seeing, and on 2012-Feb-16 and 2012-Feb-17 in very cloudy conditions with  $1.0\text{--}3.0''$  seeing; we used the 600 lines  $\text{mm}^{-1}$  grating with a 7200  $\text{\AA}$  blaze angle (resulting in dispersion of 0.65  $\text{\AA}$ ) and the GG455 filter to block out higher-order light. Wavelength coverage varied with source position on the  $5' \times 16.7'$  slit-mask from 4400–9200  $\text{\AA}$  to 5200–9900  $\text{\AA}$  and averaged to 4850–9550  $\text{\AA}$ .

Sixteen of 29 DEIMOS multi-slit masks were observed in near-photometric conditions, with integration times  $\sim 2700\text{--}4800$  s. We used the DEEP2 DEIMOS data reduction pipeline to reduce these data<sup>29</sup>. Of 930 DEIMOS HSG targets, 499 were spectroscopically confirmed. 324 of those 499 (65%) were confirmed in near-ideal conditions and are also marked with asterisks in Table 2.

Redshift identification was carried out through the identification of multiple spectral signatures, primarily with the [OII] doublet, [OIII], H $\beta$ , H $\alpha$ , [NII], Ca H & K absorption and the Balmer break, H $\gamma$ , Ly $\alpha$ , and the Lyman break (given in order of decreasing occurrence in the sample). A minority of sources were identified by CIII], CIV and HeII emission (all sources identified via features in the rest-frame ultraviolet are discussed in C12). Full spectroscopic details of all confirmed  $z < 2$  HSGs are given in Table 2 (available online in full). The reliability of redshift identifications is also given in Table 2, rated on a scale of  $q_z=1\text{--}5$ , where 5 is best. Sources with multiple feature identifications have  $q_z \geq 3$ , and sources with single line identifications have  $q_z = 1\text{--}2$ . When visually inspecting the spectra for our targets, redshifts were graded on a wider scale, with some sources having  $q_z=0$  (poor) or  $-1$  (non-existent). These sources’ potential redshifts are not reported in this paper due to unreliability.

There are more HSGs with unconfirmed redshifts (826) than there are with redshifts (767). The vast majority of the unconfirmed sample is unconfirmed due to poor weather including cloud-cover and poor seeing (54% of sources were observed in sub-optimal conditions). The average spectroscopic yield during good weather was  $60 \pm 20\%$  while the poor weather yield was only  $15 \pm 10\%$ . The remaining unconfirmed sources either very red faint continuum without identifiable spectral features (20%) or no continuum whatsoever (80%). These sources are potentially misaligned on the slit (which is based on an IRAC and  $i$ - or  $z$ -band image when available) or are too optically obscured to be detected in bright emission

<sup>29</sup> The analysis pipeline used to reduce the DEIMOS data was developed at UC Berkeley by Michael Cooper with support from NSF grant AST-0071048

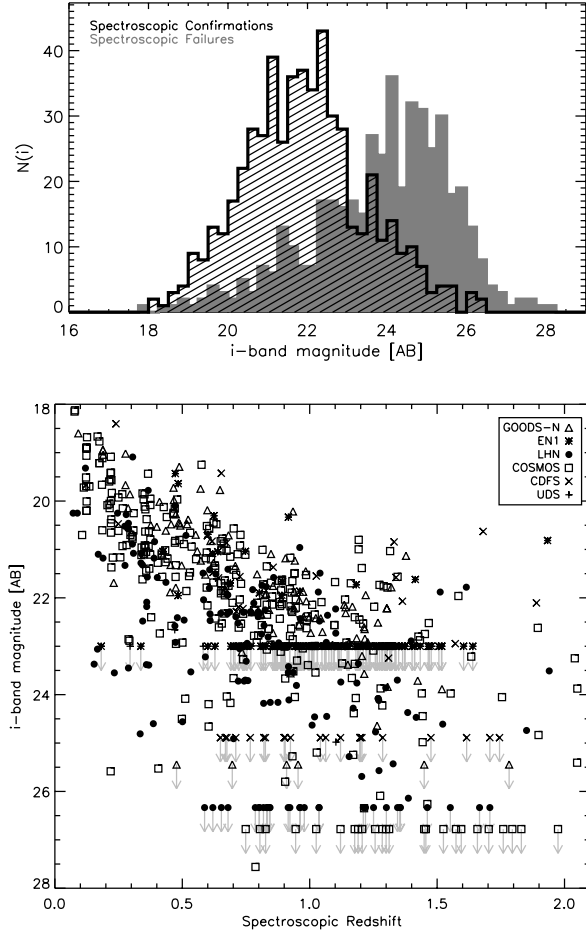

FIG. 7.— **TOP:** Distribution in  $i$ -band magnitudes of spectroscopically confirmed (hashed area) and unconfirmed sources (filled gray area). There is clearly a bias in sources with spectroscopic confirmations being brighter at  $i$ -band magnitude, also much more likely to sit at lower redshifts. However, note that for sources not included on this plot—those undetected in  $i$ -band—the spectroscopic success rate is 39%, lower than the same fraction for sources with  $i$ -band detections, 54%, although not as low as one might expect for very optically faint sources. This is likely caused by many sources being confirmed through bright emission lines which can contribute minimally to broad-band photometry. **BOTTOM:** The  $i$ -band magnitude against redshift for sources with confirmed redshifts. At the bright end,  $i < 22$ , sources show a clear trend with redshift, while many sources (marked as upper limits, according to the imaging depths in each field) have no available  $i$ -band photometry. Clearly  $i$ -band magnitude strongly impacts the likelihood of measuring a spectroscopic redshift, a concept which is explored when measuring the spectroscopic completeness, shown in Figure 12.

lines with a  $\sim 1$ – $2$  hr integration. They could also be at  $z \gtrsim 3$ , thus intrinsically much more difficult to detect optically.

Since we have very limited constraints on the spectroscopic failures, we emphasise that our sample is spectroscopically incomplete. We use photometric redshifts and inferences on the redshift distribution itself in § 3.2 to estimate the spectroscopic completeness as a function of redshift.

### 3.1. Biases in Spectroscopic Confirmations

Here we quantify the biases of our spectroscopic observations by analyzing sources which failed to yield spectroscopic identifications. This is arguably the most dif-

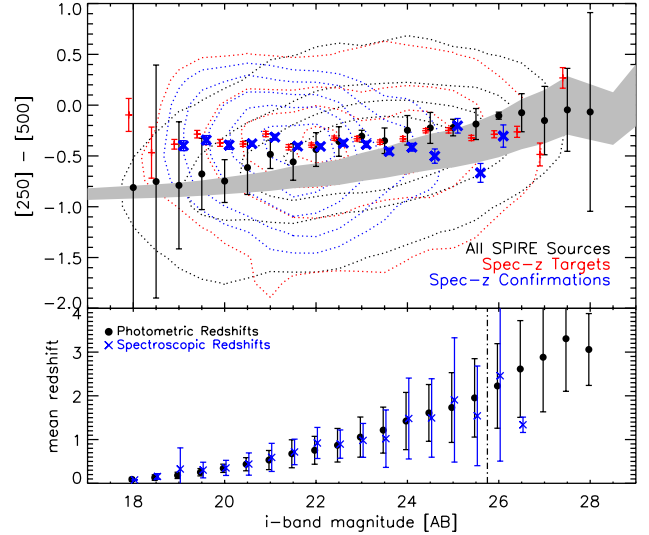

FIG. 8.— Relationship between  $i$ -band magnitude and SPIRE color,  $[250] - [500] = -\log(S_{250}/S_{500})$ . SPIRE color becomes redder with fainter magnitudes, which is expected given the redshift- $i$ -band magnitude relationship seen in Figure 7 and an assumption of constant dust temperature from low to high redshifts. The locus of all  $>3\sigma$  SPIRE sources in the upper panel consists of  $\sim 5000$  sources in the COSMOS field (black dotted contours and black points, the mean SPIRE color for  $i$  magnitude bins). Red dotted contours and points represent the distribution of spectroscopic targets ( $\sim 1600$  sources across all fields) and blue represent sources with spectroscopic confirmations, clearly skewed towards brighter  $i$ -band magnitudes. In the bottom panel we compute the mean photometric and spectroscopic redshift for the same colored samples from the plot above, and see agreement down to  $i_{AB} \approx 25.5$  (vertical dot-dashed line). At top, the gray band represent the expected SPIRE colors at the mean photometric redshift per  $i$ -band magnitude bin for dust temperatures ranging from 30 K to 50 K. Within uncertainty, the full sample follows this expectation, while the spectroscopic sample deviates toward redder colors at brighter  $i$ -band magnitudes.

ficult completeness to quantify, since it requires some knowledge of the redshift distribution of sources which are: (a) the most optically obscured, (b) have featureless continua, or (c) have observed-frame emission lines outside of the wavelength range of our observations (this redshift range is  $1.6 \lesssim z \lesssim 3.2$  for DEIMOS observations and  $1.6 \lesssim z \lesssim 1.7$  for LRIS observations). Figure 7 shows the optical  $i$ -band magnitude distributions for sources spectroscopically confirmed and unconfirmed, and  $i$ -band magnitude against redshift. This makes it clear that optical  $i$ -band magnitude need not be very bright for a spectroscopic identification based on emission lines, and that optical magnitude itself does not constrain redshift, given the number of sources at low- $z$  which are undetected in the  $i$ -band. However, it is clear that there is an overall trend with redshift at brighter magnitudes  $i < 22$ , with very few sources at these magnitudes at  $z > 0.5$ . In that sense, it is also clear from Figure 7 that optically bright sources are more likely to be spectroscopically confirmed than those which are faint; the mean  $i$ -band magnitude of spectroscopically confirmed sources is  $i_{AB} = 22.1$ , while for unconfirmed source it is  $i_{AB} = 23.8$ .

Prior studies of optical photometric properties of infrared starburst galaxies find poor corespondence between optical magnitude, IR luminosity and redshift (e.g. Chapman *et al.* 2004, 2005). This makes it quite difficult to estimate the redshift distribution and IR lumi-

FIG. 9.— The spectroscopic redshift distribution of HSGs. Since the majority of our 767 spectroscopically confirmed sources were observed with DEIMOS (66%), the redshift range  $z=1.6-3.2$  (hashed area) is sparsely populated (only two sources within this range are DEIMOS identified, both bright quasars). Distribution of photometric redshifts for the sample of spectroscopically targeted HSGs is shown as the dotted line, consistent at  $z \lesssim 1.5$  but suggesting a significantly decreased spectroscopic yield at  $z > 1.5$ .

nosities of the optically faint targets for which we fail to measure redshifts. Without redshift information, we must rely on color information to infer if the optically fainter targets have a significantly distinct redshift distribution (this also assumes SPIRE-color varies with redshift and dust temperature is roughly fixed). Figure 8 shows how SPIRE color relates to  $i$ -band magnitude for the entire parent galaxy sample of  $>3\sigma$  SPIRE sources, spectroscopic targets, and also spectroscopic confirmations. This indicates that SPIRE colors should become redder with fainter  $i$ -band magnitude, assuming a constant temperature and redshift range. The mean redshifts – photometric and spectroscopic – per  $i$ -band bin are self-consistent, indicating no strong bias in the spectroscopic redshift distribution with  $i$  magnitude. Note however that the analysis as presented in Figure 8 excludes sources (a) without photometric redshifts, and (b) without  $i$ -band counterparts. The variation of SPIRE color with redshift, along with the perceived bias of our spectroscopic sample towards redder colors at bright magnitudes, is addressed further in § 3.5.

Of the spectroscopically confirmed subsample,  $65 \pm 15\%$  are  $250\mu\text{m}$ -peaking (meaning  $S_{250} > S_{350} > S_{500}$ ),  $23 \pm 14\%$  are  $350\mu\text{m}$ -peaking ( $S_{350} > S_{250}$  and  $S_{350} > S_{500}$ ), and  $13 \pm 9\%$  are  $500\mu\text{m}$ -peaking ( $S_{250} < S_{350} < S_{500}$ ). These values are comparable to the spectroscopic targets:  $72 \pm 12\%$  were  $250\mu\text{m}$ -peaking,  $17 \pm 9\%$  were  $350\mu\text{m}$ -peaking and  $11 \pm 6\%$  were  $500\mu\text{m}$ -peaking. This leads us to conclude that successful spectroscopic identification does not have a bias with respect to FIR SED shape.

### 3.2. Redshift Distribution

The redshift distribution of the 767 spectroscopically confirmed HSGs in this survey is shown in Figure 9. Of 767, the vast majority, 731, are at  $z < 2$ . The distribution peaks at  $z = 0.85$  with a tail of sources extend-

ing out to higher redshifts, discussed fully in a separate accompanying paper, C12. Also plotted is the distribution in photometric redshifts for all spectroscopic targets. The photometric redshift distribution peaks at the same epoch, but with a much higher fraction of sources at  $z \gtrsim 2$ . The deficit in spectroscopic redshifts at  $z > 2$  is caused by: (a) the DEIMOS ‘redshift desert’ (DEIMOS observations comprise 66% of our sample and no strong emission lines are visible within DEIMOS wavelength coverage from  $1.6 < z < 3.2$ ); and (b) by a decreasing spectroscopic completeness due to enhanced obscuration in the rest-frame ultraviolet relative to rest-frame optical. The latter point relates to the very obscured nature of infrared-luminous galaxies: the increased presence of dust implies more significant extinction in the UV and optical, with more substantial effects at bluer wavelengths.

Note that predicted redshift distributions for *Herschel* sources have been studied in detail by Amblard *et al.* (2010) and Béthermin *et al.* (2011). However, these are based on different SPIRE selection methods and are thus not directly comparable to the HSG sample discussed herein. For instance, the Amblard *et al.* distribution of  $350\mu\text{m}$ -selected sources peaks at  $z \sim 2.2$ , as seen in the upper panel of Figure 10. We extract HSGs from our sample which would satisfy their detection criteria ( $S_{350} > 35\text{ mJy}$ , with  $250\mu\text{m}$  and  $500\mu\text{m}$  SNR  $> 3$ ) for comparison and find a statistically distinct distribution from Amblard *et al.*

We also compare data with the model predictions of the expected SPIRE distributions from Lagache *et al.* (2004), Negrello *et al.* (2007) and Béthermin *et al.* (2011). While our data (both of the limited  $S_{350} > 35\text{ mJy}$  sample and the distribution of all photometric redshifts) are inconsistent with most models (particularly at the  $z > 2$  end), our results are most consistent (tested via a Kolmogorov-Smirnov statistic) with the predicted distribution of Lagache *et al.* (2004); the number of sources we observe at  $z < 1$  is notably different than the predictions from Negrello *et al.* (2007) or from the long-wavelength photometric-redshift based work of Amblard *et al.* (2010).

In the middle panel of Figure 10 we compare our results to those of Chapin *et al.* (2011) for BLAST-detected galaxies in ECDF-S, a combination of photometric redshifts (Dunlop *et al.* 2010; Ivison *et al.* 2010) and spectroscopic redshifts (Casey *et al.* 2011). Their selection is based on three different flux cuts at  $250$ ,  $350$ , and  $500\mu\text{m}$ , and when applying the same selection to our sample, we find an agreement between the median redshifts, both of which have  $\langle z \rangle \approx 1$  but with differences at both low and high-redshift. There is an additional peak in the Chapin *et al.* sample at  $z < 0.5$  which is not observed in our sample. This could be due to cosmic variance, since the BLAST ECDF-S sample probes a small volume in a single field, while our data sample multiple deep fields over a larger sampling volume. Given the DEIMOS redshift desert, comparison cannot be drawn fairly beyond  $z \sim 1.6$ .

Worth noting is the contrast of these redshift distributions with the  $850\mu\text{m}$ -selected SMG redshift distribution (Chapman *et al.* 2005; Yum *et al.* 2012), which peaks at  $z \sim 2.2$  (see bottom panel of Figure 10). The peak in  $850\mu\text{m}$ -selected galaxies occurs at earlier epochs due

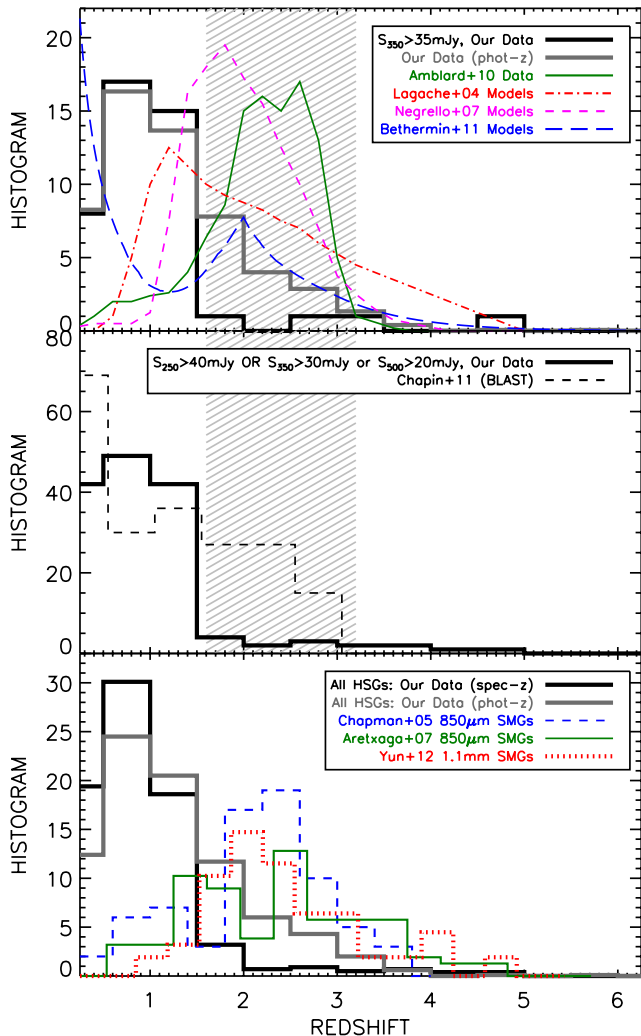

FIG. 10.— Comparison of our redshift distributions to those in the literature; at top, we compare to the Amblard *et al.* (2010) distribution (green) for sources selected at  $350\,\mu\text{m}$  above  $35\,\text{mJy}$  (with  $>3\sigma$  significant detections at both  $250\,\mu\text{m}$  and  $500\,\mu\text{m}$ ). We also compare the full distribution of photometric redshifts of our targets (thick, solid gray) to the model distributions from Lagache *et al.* (2004), Negrello *et al.* (2007), and Béthermin *et al.* (2011) (dot-dashed red, dashed magenta, and long-dashed blue respectively). Neither observed distribution (spectroscopic and photometric) shows good agreement with the models, however the Lagache *et al.* model (which peaks at  $z \sim 1$ ) agrees best with our data. The middle panel compares to the redshift distribution of Chapin *et al.* (2011) of for BLAST-bright galaxies in ECDF-S. Given the limited number of sources in the BLAST analysis (and that they are all identified in ECDF-S, a small volume) we conclude that these two distributions are consistent within uncertainty. At bottom we compare the HSG redshift distribution to those of  $850\,\mu\text{m}$ – $1.1\text{mm}$  selected SMGs, which peak at  $z \approx 2.2$ – $2.6$  due to the longer wavelength selection. The HSG distribution is taken from Figure 9 and scaled down 10 times in total number for direct comparison.

to the selection wavelength:  $850\,\mu\text{m}$  is more sensitive to lower luminosity/colder sources at higher redshifts and less sensitive to warmer sources at low redshift. SPIRE selection is not constant in luminosity out to very high redshifts like  $\sim 1\text{mm}$  selection is, but it has the benefit of probing the peak of the infrared SED at  $z \sim 1$ – $2$ , thus is not likely to miss or select against sources at a given luminosity due to their warmer SED shape.

### 3.3. Comparison to photometric redshifts

Photometric redshifts are far easier to obtain on larger samples of galaxies than spectroscopic redshifts, and whenever the latter become available, it is important to test the reliability of the former. Many large statistical studies are now motivated exclusively by use of large catalogs of photometric redshifts; here we explore possible underlying biases which might persist in HSG photometric redshifts and what might cause them. Note that all photometric redshifts used in this paper are calculated from ultraviolet through near-infrared photometry and exclude any long-wavelength data  $>8\,\mu\text{m}$  (the catalogs used in this analysis are described at the end of § 2).

Spectroscopic and photometric redshifts are plotted against one another in Figure 11. From this we measure that HSG photometric redshifts have a mean rms scatter of  $\sigma = \Delta z / (1 + z_{\text{spec}}) = 0.29$ , characteristically a factor 3–4 times worse than the photometric redshifts for regular field galaxies (Ilbert *et al.* 2010, measure  $\Delta z / (1 + z_{\text{spec}}) = 0.07$  for galaxies with spectral confirmations in COSMOS). This might be surprising given that the majority of sources in this comparison come from fields with deep, multi-band photometry (e.g. COSMOS, LHN). Why are the photometric redshifts of infrared-bright galaxies substantially worse than those of most field galaxies?

One might think that the disagreement originates from source blending or mismatching due to the large beam-size of infrared observations. However, we do not expect blending or mismatching to occur since the photometric redshifts taken from the source catalogs are matched to our spectroscopic targets' position within  $\lesssim 1''$  (i.e. even if a SPIRE source's counterpart is mistakenly identified, we would still expect the false counterpart's photometric redshift to agree with its spectroscopic redshift). Since mismatched counterparts is not likely to be the source of the photometric redshift scatter, the scatter is likely due to some other property of the infrared-selected sample.

If the  $z_{\text{phot}} - z_{\text{spec}}$  disagreement is not caused by mismatched counterparts, then what intrinsic physical processes could explain less reliable photometric redshifts in infrared-selected galaxies? Direct detection at far-infrared wavelengths implies two things about a galaxy: (i) it has a significant dust reservoir which has absorbed more energetic light and re-radiated it in the far-infrared, and (ii) it has a high star-formation rate (since FIR luminosity scales directly to star formation rate; Kennicutt 1998). The first point highlights that the galaxy's emission at rest-frame ultraviolet and optical wavelengths—emitted by young, hot stars—is being obscured and scattered by dust; as a result, infrared-selected galaxies are optically fainter than their less-dusty counterparts of similar redshifts and stellar masses. The second point, that infrared-galaxies have intrinsically higher star formation rates than most 'normal' field galaxies follows from the implied infrared luminosities of the infrared-selected samples. The vast majority of field galaxies have star formation rates  $< 10\,M_{\odot}\,\text{yr}^{-1}$  (e.g. the vast array of 200K galaxies in COSMOS which are fit with stellar population templates from Bruzual & Charlot 2003). In contrast, most infrared-selected galaxies satisfy  $L_{\text{IR}} > 10^{11}\,L_{\odot}$ , which implies star formation rates of  $> 17\,M_{\odot}\,\text{yr}^{-1}$  or  $L_{\text{IR}} > 10^{12}\,L_{\odot}$  which implies

FIG. 11.— **TOP:** Redshift distributions for HSGs shown on a logarithmic scale: the full spectroscopic sample (solid black); spectroscopically confirmed sources with photometric redshifts ( $z_{\text{spec}}|z_{\text{phot}}$ , in other words “ $z_{\text{spec}}$  given  $z_{\text{phot}}$ ,” dashed red); spectroscopically confirmed sources without photometric redshifts ( $z_{\text{spec}} \setminus z_{\text{phot}}$ , in other words “ $z_{\text{spec}}$  take away  $z_{\text{phot}}$ ,” dotted magenta); photometric redshifts (solid blue); and photometric redshifts for spectroscopically confirmed sources ( $z_{\text{phot}}|z_{\text{spec}}$ , in other words “ $z_{\text{phot}}$  given  $z_{\text{spec}}$ ,” dashed green). The DEIMOS redshift desert is shown as a hashed area. **BOTTOM:** Spectroscopic versus photometric redshift for successfully identified targets which have photometric redshifts (431 sources out of 767). The photometric redshifts were taken from Strazzullo *et al.* (2010) (Lockman Hole North), Rowan-Robinson *et al.* (2008) (ELAIS-N1, UDS), Ilbert *et al.* (2010) (COSMOS) and Cardamone *et al.* (2010) (ECDFS) with associated uncertainties on  $z_{\text{phot}}$  shown. The mean RMS scatter at is  $\Delta z/(1+z_{\text{spec}}) = 0.29$ , notably worse than the expected photometric redshift accuracy of photometric redshifts of ‘normal’ starburst galaxies.

$> 170 M_{\odot} \text{ yr}^{-1}$ . Higher star formation rates translate to brighter rest-optical emission lines and higher line-to-continuum ratios.

How might dust obscuration and enhanced line-to-continuum ratios impact the reliability of photometric redshifts for HSGs? The first effect is straightforward: the fainter a galaxy is in the optical, the more difficult it is to put a reliable constraint on its photometric red-

shift. Since HSGs are optically fainter than ‘normal’ galaxies which harbor less dust, this is one reason HSG photometric redshifts are less reliable. The second effect comes from the ‘contamination’ of bright emission lines of the optical broad band filters used to compute the sources’ photometric redshifts. Although emission lines can contaminate the broad band magnitudes for both normal and dusty galaxies, dusty galaxies have comparably fainter continuum (or rather, a more significant contribution from emission lines). Also, despite some efforts to account for emission lines in photometric redshift code algorithms (by including them in the templates used for the fitting), none of the existing optical templates in the literature (e.g. Calzetti, Kinney & Storchi-Bergmann 1994; Bruzual & Charlot 2003) include models with extremely high star formation rates and dust content as exists in HSGs, hence the poorer  $z_{\text{phot}} - z_{\text{spec}}$  agreement.

The influence of dust obscuration on photometric redshift estimates is not completely straightforward in that dust is not necessarily expected to extinct optical flux uniformly across all wavelength regimes. Sources with high phot-zs and low spec-zs can be explained by differential blue-to-red obscuration whereby the galaxies dropout in several blue bands due to stronger absorption of higher energy photons. The handful of sources with low photometric redshifts and high spectroscopic redshifts ( $z > 2$ ) are described in detail in C12; these are thought to disagree due to differential obscuration of resonant emission-line photons and continuum (e.g. Neufeld 1991), whereby emission lines are not extinguished as significantly as stellar emission continuum. This is also highly dependent on viewing geometry, but the observation holds that photometric redshifts of dusty galaxies are significantly worse than they are for normal field galaxies which contain less dust. Caution should be exercised when using large photometric datasets to quantify the aggregate properties of infrared-selected samples.

### 3.4. Spectroscopic Completeness

With a lack of any better constraint on the redshift distribution of unconfirmed HSGs, we use our targets’ photometric redshifts (those with and without spectroscopic redshifts) to constrain spectroscopic completeness as a function of redshift. Figure 12 (top panel) contrasts the spectroscopic and photometric redshift distributions by instrument, since LRIS and DEIMOS observations have different wavelength coverage, thus different redshift completeness levels. Measuring spectroscopic completeness requires an estimate of the underlying redshift distribution for the whole population, including those without photometric redshifts. The only constraint we have on sources without photometric redshifts is from those spectroscopically observed, shown in Figure 11 at top, consistent with the distribution in photometric redshifts. Therefore, a scaling correction factor,  $C$ , is applied to the distribution of photometric redshifts to account for the sources without photometric redshifts. Although this assumption might not be entirely correct (i.e. there might be a much higher fraction of  $z > 2$  sources which do not have photometric redshifts), the assumption that the redshift distribution is weighted at lower redshifts effectively places the lower limit of spectroscopic completeness at  $z < 2$ . If the fraction of sources without photometric redshifts is higher at high- $z$ , then

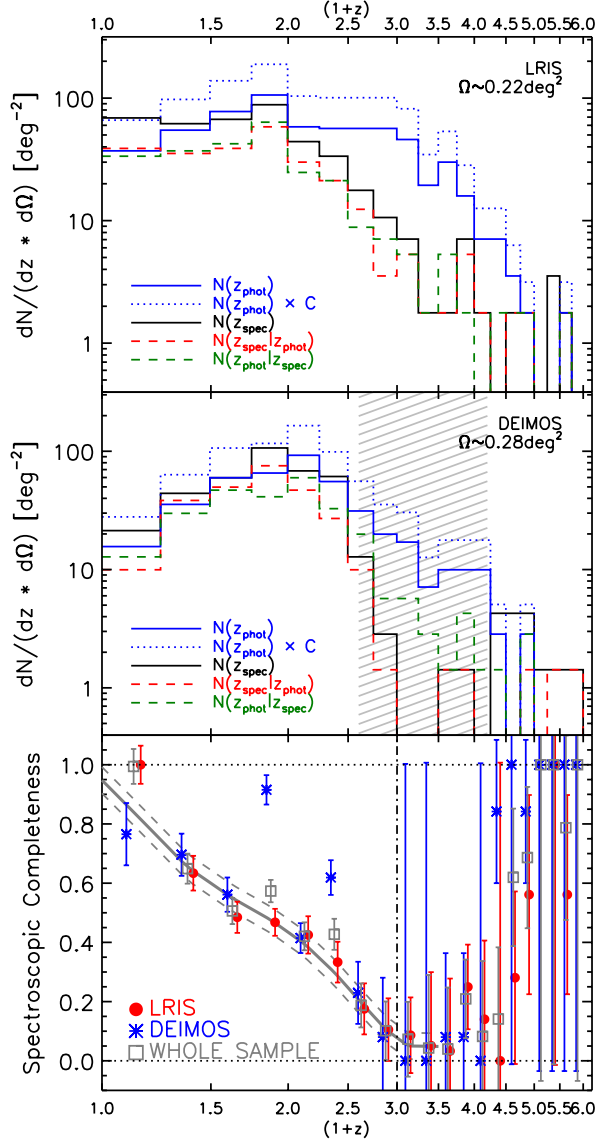

FIG. 12.— The top and middle panels show the redshift distributions of HSGs split into LRIS and DEIMOS samples. DEIMOS redshift desert is marked in the middle panel. Assuming the redshift distribution for sources without photometric redshifts resembles the distribution in photometric redshifts (see Figure 11 top panel), then we can estimate the spectroscopic completeness of our survey, bottom panel, by dividing the spectroscopic redshift distributions (by instrument) by the photometric redshift distribution scaled up to account for sources without photometric redshifts. From this, we determine that survey completeness cannot be constrained at  $z > 2$  (due to small number statistics) which is why that sample is discussed in a separate paper. The best-fit curve at  $z < 2$  (plotted in gray with dashed lines showing uncertainty) is used later to estimate the total contribution of HSGs to the SFRD. The two ‘outlier’ high-completeness DEIMOS points are discussed in the text.

the spectroscopic completeness measurement at  $z < 2$  will increase. The spectroscopic completeness is measured as a function of redshift by dividing the distribution in spectroscopic redshifts by that of the scaled up photometric redshifts (i.e.  $N(z_{\text{spec}})/(C \times N(z_{\text{phot}}))$ ). This spectroscopic completeness estimate is shown in the bottom panel of Figure 12. As expected, it declines

FIG. 13.— *Herschel*-SPIRE color with redshift, where color is given as a magnitude difference between SPIRE bands, such that high values correspond to red colors. In light gray are SPIRE colors of the entire photometric HSG sample from the COSMOS field; dark gray points are our spectroscopic sample. The mean of the spectroscopic sample and photometric sample is shown as black circles and dark red squares, respectively, with associated uncertainties. Overplotted are tracks of SEDs with fixed dust temperature, 20 K (red), 30 K (orange), 40 K (green), 50 K (blue), and 60 K (purple). We see no significant color evolution in the HSG sample with redshift; this is primarily due to selection properties of the sample.

over  $0 < z < 2$  and then is unconstrained at  $z > 2$  due to limited samples. The DEIMOS completeness estimate has two ‘outlier’ points at  $z \sim 0.8$  and  $z \sim 1.3$ ; this is caused by the enhanced sensitivity of DEIMOS from 6500–7400Å (where LRIS often has a gap in coverage), and 7600–9000Å (where our LRIS observations were slightly more prone to skyline contamination). Since the completeness becomes unconstrained at  $z > 2$ , we choose  $z = 2$  as a natural boundary at which to divide the sample, addressing the well-constrained  $z < 2$  population in this paper, while discussing the full sample of spectroscopically incomplete  $z > 2$  sources in C12.

### 3.5. SPIRE Color with Redshift

Recalling from the discussion in § 3, our spectroscopic HSGs sample the underlying distribution of all SPIRE sources well in SPIRE color, despite a bias in  $i$ -band magnitude (where brighter optical sources are more likely to

be spectroscopically confirmed). Figure 8 showed that the mean redshift and SPIRE color per  $i$ -band magnitude of our spectroscopic HSGs is drawn from the parent sample of SPIRE sources without significant bias. While this hinted at the evolution of SPIRE color with redshift, we can test this evolution directly using our spectroscopic HSGs and larger photometric redshift samples from COSMOS (Ilbert *et al.* 2010).

Assuming that most infrared starbursts can be described with a 35 K dust SED (Chapman *et al.* 2005; Rieke *et al.* 2009), one would expect low redshift sources to have blue SPIRE colors and high redshift sources to have red SPIRE colors (e.g. Cox *et al.* 2011; Roseboom *et al.* 2012). Figure 13 plots the [350]–[250], [500]–[350], and [500]–[250] colors against redshift, where [250] is defined as a 250  $\mu$ m magnitude, i.e.  $-2.5\log(S_{250})$ . We see no strong trend in SED shape with spectroscopic redshift. While it might be expected that high- $z$  sources are significantly more ‘red’ than ‘blue’ low- $z$  sources, this interpretation is simplistic since it assumes no evolution in dust temperature, no relationship between dust temperature and luminosity, and ignores the impact of population selection effects. Overplotted on Figure 13 are the color-redshift tracks for SEDs of fixed dust temperature systems from 20–60 K; they evolve more strongly with redshift than our data, particularly notable in [500]–[250] color.

The dispersion on the SPIRE colors in both the spectroscopic and photometric samples imply a wide range of dust temperatures. This highlights that far-infrared flux densities and colors cannot be used exclusively as a proxy for redshift. Notwithstanding the large dispersion in SPIRE colors, two main observations can be drawn from Figure 13: (a) that the mean SPIRE colors do not redden significantly with redshift as might be expected; and (b) at low- $z$  ( $z < 0.5$ ) our spectroscopic sample is redder, i.e. cooler, than the photometric redshift sample.

Both of these observations can be understood by investigating how SPIRE selection works in the  $L_{\text{IR}} - T_{\text{dust}}$  plane, discussed fully in § 4.4. Dust temperature increases with luminosity (which is partially a selection effect against high- $z$  cold systems and partially thought to be a real correlation). Since the highest-redshift sources in our sample are significantly more luminous than our lower redshift sources, the correlation between  $L_{\text{IR}}$  and  $T_{\text{dust}}$  translates to a correlation between  $z$  and  $T_{\text{dust}}$ . This results in roughly constant SPIRE colors with redshift. At  $z < 0.5$ , we note that our spectroscopic survey is limited in the number of very luminous ( $\gtrsim 10^{12} L_{\odot}$ ) galaxies it can detect simply due to sky area probed ( $\approx 1 \text{ deg}^2$ ); since (in § 4.4) we will observe that more luminous HSGs are hotter, it is natural that a sample of HSGs with photometric redshifts (covering a much larger area than our spectroscopic survey) will probe naturally warmer HSGs. This gives rise to the ‘redder’  $z < 0.5$  spectroscopic sample. Although the two redshift bins at  $1.6 < z < 2.0$  seem bluer than at any other redshift, we note that the number of sources in these redshift bins is significantly fewer (and the observation is not the same for the much larger sample of sources with photometric redshifts in that range).

#### 4. RESULTS

##### 4.1. Summary of Spectra and Redshifts

Table 2 lists the positions, redshifts, SPIRE flux densities, 24  $\mu$ m and radio flux densities, luminosities and dust temperatures for the full sample of  $z < 2$  spectroscopically confirmed HSGs. Sample spectra of a variety of spectroscopically-confirmed targets of the  $z < 2$  confirmed HSG sample are shown in Figure 14. Of 1594 targets with  $>3\sigma$  SPIRE detections, 767 have spectroscopically identified redshifts from these data, 731 of which are at  $z < 2$ . By field, there are 288 in COSMOS, 163 in LHN, 119 in GOODS-N, 139 in EN1, 51 in CDFS, and 8 in the UDS. The total sky area probed by this redshift survey is  $\sim 0.93 \text{ deg}^2$ .

Besides the selection and spectroscopic biases mentioned in the previous section, the spectroscopic yield for sources varied strongly as a function of observing conditions and integration time, anywhere from 15% to 80%. However, unlike the selection and spectroscopic biases, this variation in yield is much easier to correct. While the full  $0.93 \text{ deg}^2$ , 767 source sample is used in most analysis, only the sources surveyed under photometric conditions to full survey depth, i.e. 13 LRIS masks and 16 DEIMOS masks, covering an area of  $0.43 \text{ deg}^2$ , are used to measure quantities which rely on accurate measurements of source density (e.g. the integrated infrared luminosity function and star formation rate density).

##### 4.2. Infrared SED Fitting

We note that best-fit SED template fits from Chary & Elbaz (2001), Dale *et al.* (2001), Dale & Helou (2002), Siebenmorgen & Krügel (2007) or Draine & Li (2007) recover  $L_{\text{IR}}$  well, however we choose not to fit our data to these complex models given the limitations of our data and the variation in SED shapes. As discussed in Casey (2012) at length, the templates should be used with caution when the number of free parameters in the templates exceeds the number of data points; this is certainly the case for those sources which have three to five photometric FIR data points. The dust temperature range of these SED templates is restricted to the  $20 < T_{\text{dust}} < 60 \text{ K}$  range and quantized. For these reasons, we opt to use the functional fits in lieu of FIR SED templates.

Measuring infrared luminosities and dust temperature for SPIRE galaxies is performed by fitting a modified blackbody SED extrapolated over the rest-frame FIR to existing photometric data. In addition to the SPIRE flux densities, we use photometry from *Herschel*-PACS at 100  $\mu$ m, and 160  $\mu$ m in Lockman Hole North and COSMOS, and *Spitzer*-MIPS at 24  $\mu$ m, and 70  $\mu$ m where available.

We fit the data for each galaxy to a modified blackbody fit of general opacity coadded to a mid-infrared power law, where the flux density,  $S_{\nu}$  at rest-frame frequency  $\nu$  is represented by

$$S_{\nu} \propto (1 - e^{-\tau(\nu)}) B_{\nu}(T) \\ = N_{\text{bb}} \frac{(1 - e^{-\tau(\nu)}) \nu^3}{e^{h\nu/kT} - 1} + N_{\text{pl}} \nu^{-\alpha} e^{-(\nu/\nu_c)^2} \quad (1)$$

where  $\tau(\nu) = (\nu/\nu_0)^{\beta}$  is the optical depth (Draine 2006),  $\beta$  is the emissivity, the physical dust temperature is  $T$ , and  $\nu = c/\lambda_0$  ( $\lambda_0 = 200 \mu\text{m}$ ) is the frequency where optical depth is unity (see Casey 2012, for full details on the SED fitting method). Note that the physical dust

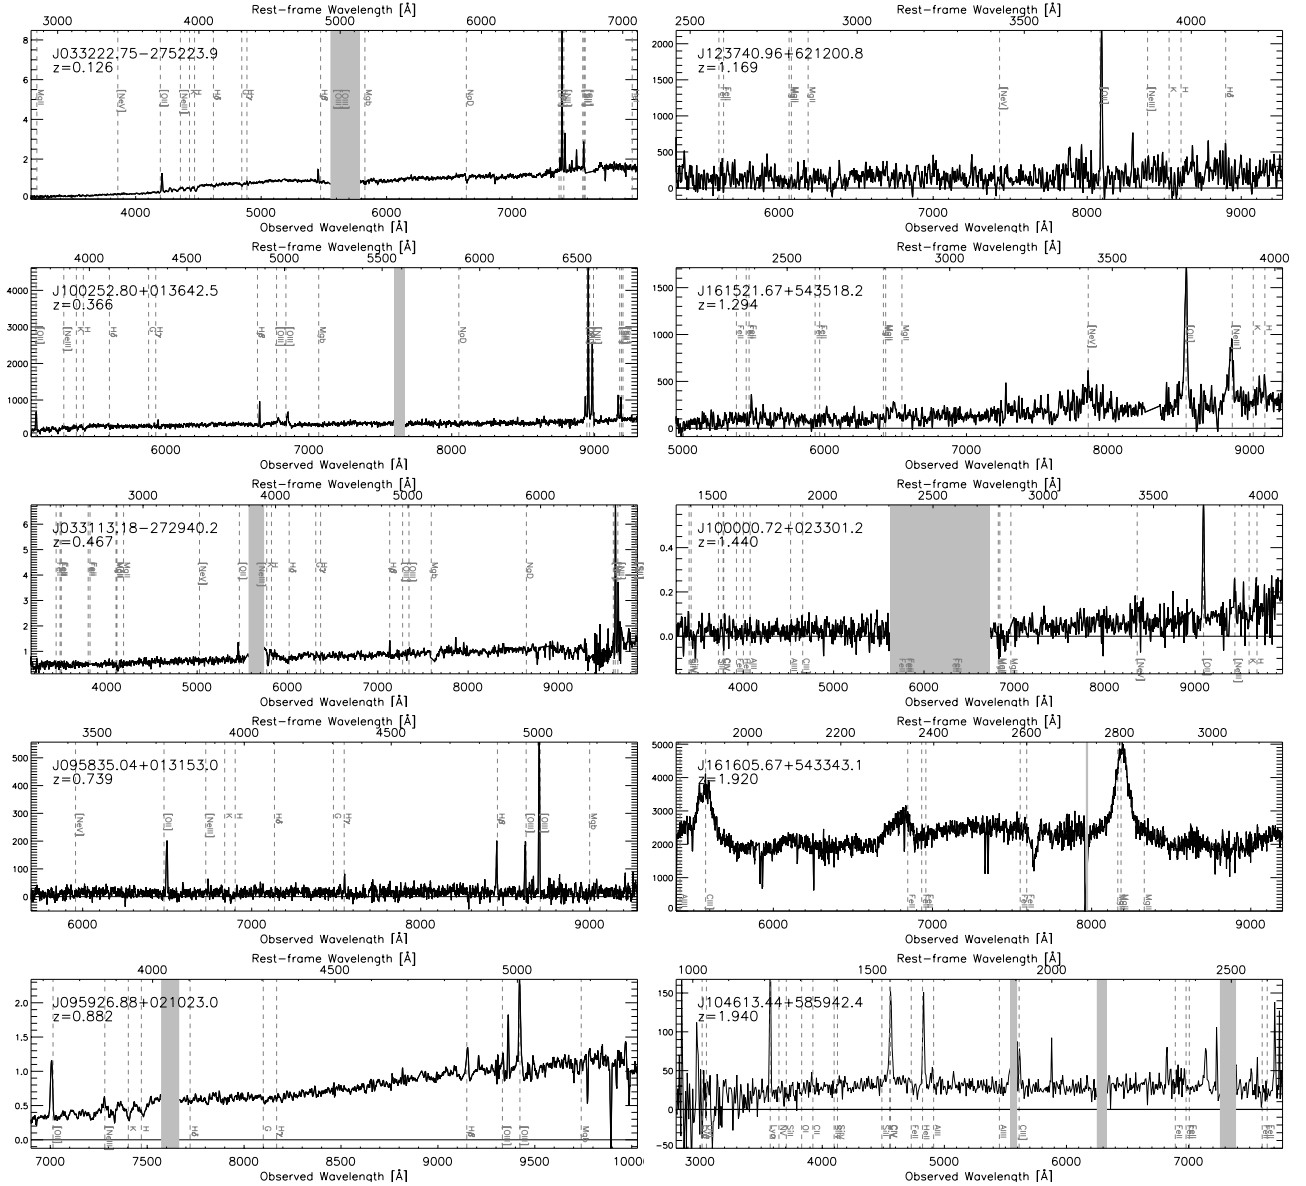

FIG. 14.— Ten sample spectra of *Herschel*-SPIRE selected galaxies ranging in redshift from  $z = 0.126$  to  $z = 1.940$ . These sample spectra span a range of spectral types and include both LRIS and DEIMOS observations. The flux scales are in arbitrary, uncalibrated flux units. Spectra of the  $z > 2$  HSGs are given in full in C12. Individual spectra for sources given in Table 2 are available on request.

temperature,  $T$ , used in this equation is not the same as the dust temperature used for the remainder of the paper; we choose to measure a “peak-SED” dust temperature, called  $T_{\text{dust}}$ , which is the dust temperature measured from the peak of the SED via Wien’s law.  $T_{\text{dust}}$  is less dependent on model parameters than  $T$ , so is more easily compared to dust temperatures measured via other means (see Casey 2012, , Figure 2 for more detail).  $N_{\text{bb}}$  and  $N_{\text{pl}}$  are the coefficients of the modified black body and power law terms, where  $N_{\text{pl}}$  is set such that the two functions are equal at the frequency,  $\nu_c$ , where the gradient of the black body is equal to the slope of the power law,  $\alpha$ . We allow  $\alpha$  to vary with the range  $0.5 < \alpha < 5.5$  for sources with  $24\mu\text{m}$  measurements (all sources except those in GOODS-N). If we have no mid-infrared measurements for the source, we fix  $\alpha = 2.0$ , which is the mean value for the rest of the SPIRE galaxies in our sample and a common value used throughout the literature (see Younger *et al.* 2009; Magnelli *et al.*

2010; Hilton *et al.* 2012). Since our observations cover a relatively narrow wavelength range without measurements on the Rayleigh-Jeans tail in the millimeter (from  $\approx 850\mu\text{m}$ – $2\text{mm}$ ), we cannot constrain  $\beta$  in a meaningful way (except for very low-redshift sources where the SPIRE points sit on the Rayleigh-Jeans tail). For consistency in our fitting technique, we decided to fix the emissivity to  $\beta = 1.5$  (this is a commonly chosen value of  $\beta$  in the literature, e.g. Chapman *et al.* 2005; Pope *et al.* 2005; Younger *et al.* 2009). There is very little change in derived  $L_{\text{IR}}$  or  $T_{\text{dust}}$  by fixing  $\beta$  within the 1–2 range, so we determine this procedure to be reasonable.

Figure 15 illustrates ten example SED fits using our method, contrasting them with both radio-implied FIR SEDs (from the radio/FIR correlation) and extrapolations from  $24\mu\text{m}$  assuming a nominal template for high- $z$  ULIRGs, like the Pope *et al.* (2008) composite SED.

Table 2 lists the 8–1000  $\mu\text{m}$  IR luminosities and dust temperatures for the whole sample, and Figure 16 shows

FIG. 15.— Ten example FIR SED fits to SPIRE-selected starbursts: three from LHN; three from COSMOS; two from EN1; and two from GOODS-N. The FIR data points (SPIRE, and PACS, where available) are shown with  $1\sigma$  uncertainties, and our best-fit modified blackbody SED is shown in black (see § 4.2 for details on SED fitting). The underlying cold-dust blackbody dominating the FIR portion  $>40\mu\text{m}$  of our SED is shown as a dashed line. For sources which have *Spitzer*-MIPS coverage, we overplot the mean composite SED of SMGs from Pope *et al.* (2008) normalised to  $24\mu\text{m}$  (red). Sources with 1.4GHz VLA coverage have another SED overplotted (blue): a modified blackbody inferred from assuming the radio/FIR correlation holds (with  $q_{\text{IR}}$  as given in Ivison *et al.* 2010) with  $T_{\text{dust}}$  best fit to the data. Gray vertical lines mark rest-frame  $8\mu\text{m}$ ,  $40\mu\text{m}$ , and  $1000\mu\text{m}$ . We note that the cold-dust blackbody only dominates the SED in the  $40\text{--}1000\mu\text{m}$  wavelength range, although IR luminosity is computed across the range  $8\text{--}1000\mu\text{m}$ , using the combination of IR modified blackbody and mid-infrared power law.

FIG. 16.— The  $8\text{--}1000\mu\text{m}$  integrated infrared luminosity against redshift for *Herschel*-SPIRE spectroscopically identified sources. The lower luminosity limits at the selection wavelengths are marked, both for the prior source catalogs at  $24\mu\text{m}$  ( $S_{24} > 100\mu\text{Jy}$ , dashed line) and 1.4GHz ( $S_{1.4} > 25$  or  $40\mu\text{Jy}$ , long dashed and dot-dashed lines), and SPIRE wavelengths (colored hashed regions). The detection limits at the SPIRE bands change with SED shape; we measure the dust temperatures of galaxies (via Wien's law) selected in each filter to determine the range of peak-SED dust temperatures to integrate between to calculate the IR luminosity limits at  $250\mu\text{m}$  (blue),  $350\mu\text{m}$  (yellow), and  $500\mu\text{m}$  (red). Sources selected as radio sources are marked as crosses and  $24\mu\text{m}$  sources are marked as green diamonds.

how the sources fall in luminosity versus redshift with respect to the various selection criteria. Note that the SPIRE selection criteria are not fixed in infrared luminosity since luminosity depends both on dust temperature

and flux density. Similarly, the radio and  $24\mu\text{m}$  detection limits are not absolute, since survey depths at both wavelengths vary between fields.

Figure 16 shows all spectroscopic HSGs in  $L_{\text{IR}}\text{--}z$  space. Despite the fact that our sources are identified initially by  $24\mu\text{m}$  or radio source observations, the detection threshold in  $L_{\text{IR}}\text{--}z$  space corresponds well with the SPIRE  $>3\sigma$  luminosity limit alone (at  $z < 3$ , where *Spitzer* is effectively more sensitive than SPIRE).

#### 4.3. Aggregate Infrared SEDs

While individual galaxies in our sample have at most five flux density measurements in the FIR, some with very low signal-to-noise, we can combine the measurements from many sources to infer the aggregate infrared properties of our sample in greater detail.

Figure 17 shows two composite near-infrared through radio SEDs for the entire  $0 < z < 2$  HSG sample. The first comprises the 331 sources which are radio-detected at  $z < 2$ : their flux densities are scaled so that the  $K$ -corrected radio flux density equals the mean of the sample,  $133\mu\text{Jy}$ , at the mean redshift of the sample,  $\langle z \rangle = 0.89$ . The second composite SED is constructed of all 731  $z < 2$  sources, with flux densities re-normalized to the mean infrared luminosity,  $4.1 \times 10^{11} L_{\odot}$ , and redshift,  $\langle z \rangle = 0.80$ , of the sample. The two SEDs are remarkably similar, with dust temperatures of 27 K and 30 K, and mid-infrared slopes of  $\alpha = 1.9$  and 2.1, respectively. The most noticeable difference lies in the near-infrared, where radio normalization seems to artificially wash out the stellar mass bump. The other observation to make is the spread in the radio flux densities in the IR scaled SED; although this is large ( $\sim 2$  dex, most falling within  $\sim 1$  dex scatter), we note that this could very well be due

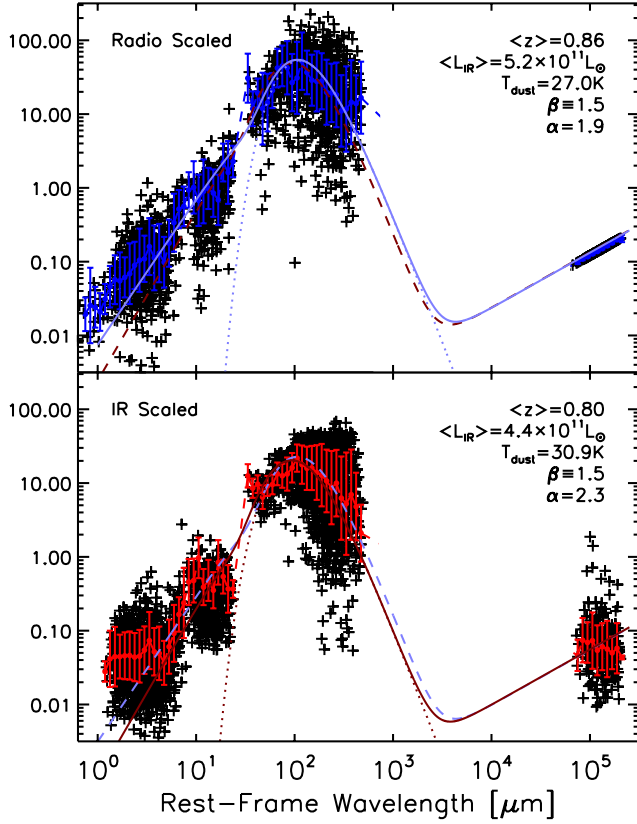

FIG. 17.— Composite infrared to radio spectral energy distributions of HSGs scaled to their radio flux densities (top; 331 radio-detected HSGs) and integrated infrared luminosities (bottom; all 767 HSGs). The best fit SED shapes (light blue, top, dark red, bottom) are remarkably similar between the two samples, with best-fit dust temperatures of 27 K and 30 K and mid-infrared slopes of 1.9 and 2.1, respectively.

to individual source variation in the synchrotron slope or bright radio AGN. Since the mean value of the radio flux densities falls within  $\pm 0.2$  dex of the expected radio flux density (from the FIR radio correlation), we deduce agreement. The overall agreement between the two radio scaled and IR scaled SEDs re-enforces that: (a) the FIR radio correlation seems to hold in this sample within uncertainty; and that (b) radio selection is not clearly biased in integrated infrared properties in comparison to  $24\mu\text{m}$  selected HSGs.

To test for luminosity and redshift evolution of infrared SED type, Figure 18 illustrates the near-infrared through radio SEDs of all  $0 < z < 2$  sources split into several infrared luminosity bins. We measure a steady increase in dust temperature with luminosity (and also consequently redshift) from  $\approx 20$  K at  $10^{10} L_{\odot}$ , to  $\approx 30$  K at  $10^{12} L_{\odot}$ , and a jump to 45 K at  $10^{12.5-13.0} L_{\odot}$ . Understanding whether or not this increase in dust temperature is due to redshift evolution, luminosity, or selection effects is difficult, due to the redshift dependence of luminosity; this issue is discussed more in context of the  $L_{\text{IR}} - T_{\text{dust}}$  plane in the next section.

An interesting conclusion can be drawn from the composite SEDs about the evolution of near- and mid-infrared properties. At lower luminosities (up to  $10^{12} L_{\odot}$ ), the near-infrared data  $< 10\mu\text{m}$  increases towards shorter wavelengths, indicative of emission from old stars (i.e. the stellar mass bump) with a local min-

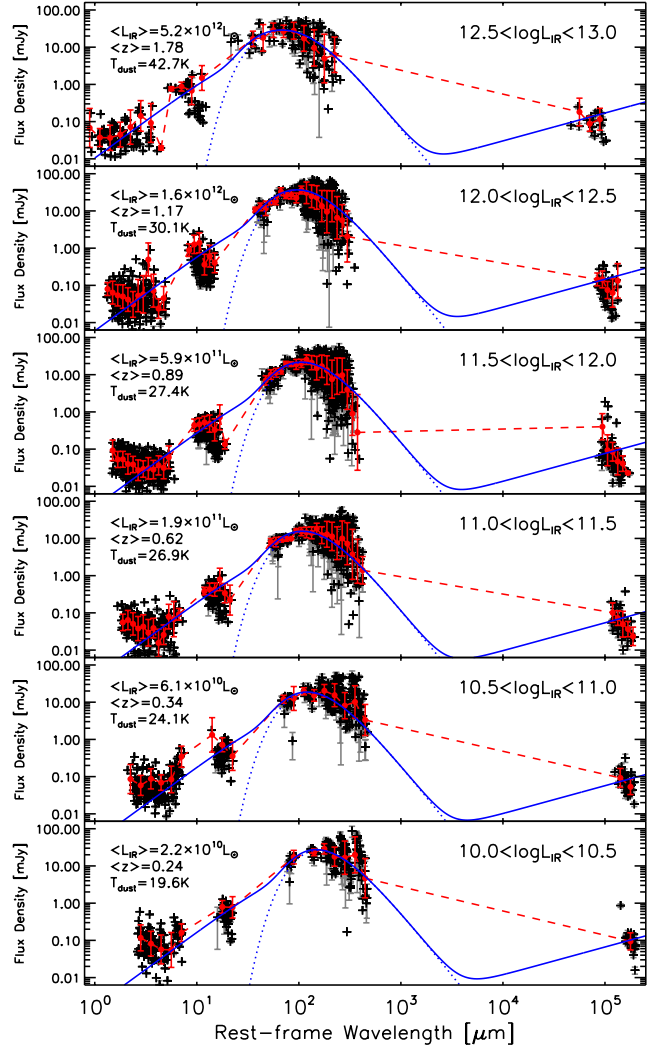

FIG. 18.— Composite infrared to radio spectral energy distributions of HSGs in six luminosity bins, from  $L_{\text{IR}} = 10^{10} L_{\odot}$  to  $10^{13} L_{\odot}$ . Flux densities are renormalized first to the mean luminosity and redshift of each bin. Infrared dust SEDs are fit to binned data (red points) from rest-frame  $8\mu\text{m}$  to  $1000\mu\text{m}$ , with fixed  $\alpha = 2.0$  and  $\beta = 1.5$ . The radio portion of the SEDs are generated by assuming the FIR/radio correlation holds; overall, these radio SEDs agree with radio data. From the SED fits, we measure a steady increase in dust temperature with luminosity, from  $T = 19$  K at  $2 \times 10^{10} L_{\odot}$  at  $\langle z \rangle = 0.23$  to  $T = 46$  K at  $5.2 \times 10^{12} L_{\odot}$  at  $\langle z \rangle = 1.81$ . We also see evidence for the evolution of near- to mid-infrared properties, most prominent in the highest luminosity bin, with detection of the  $\approx 10\mu\text{m}$  Si absorption feature (from a  $24\mu\text{m}$  flux density deficit of sources around  $z \sim 1.4$ ).

imum at  $\sim 5-6\mu\text{m}$ . In the highest luminosity bin, the prominence of the stellar bump disappears, as the emission seems to be dominated by a power law. Furthermore, the rest-frame mid-IR is unremarkable at low luminosities, largely consistent with the expected continuum flux density from our SED fit, while the highest luminosity bin shows a strong absorption feature at  $\approx 10\mu\text{m}$ , thought to be  $9.7\mu\text{m}$  Si absorption, seen in some of the most luminous local infrared galaxies, including Arp 220 (Charmandaris *et al.* 1997). This feature is detected in this composite SED only due to sources at the corresponding redshift ( $z \sim 1.4$ ) having a  $24\mu\text{m}$ -flux density deficit relative to sources at redshifts above and below

$z \sim 1.4$ .

#### 4.4. The Temperature-Luminosity Plane

Figure 19 shows our sample in  $L_{\text{IR}} - T_{\text{dust}}$  space. Overall, dust temperature increases with luminosity, which is partially attributable to our selection and partially to a real physical effect. The selection effect (that more luminous sources are hotter) stems from the nature of selection at wavelengths on the Rayleigh-Jeans tail, where hot-dust SEDs are selected against (at comparable IR luminosities). This dust-temperature selection effect was much more pronounced in the SMG population selected at  $850\ \mu\text{m}$  (see Blain *et al.* 2004; Chapman *et al.* 2004; Casey *et al.* 2009; Chapin, Hughes & Aretxaga 2009), than it is in SPIRE samples, which probe the dust SED closer to its peak and even beyond, at  $z \gtrsim 3$ . The solid lines in the left panel of Figure 19 represent SPIRE detection limits, or contours of fixed  $250\ \mu\text{m}$  flux density and redshift. When split into different redshift bins, the  $L_{\text{IR}} - T_{\text{dust}}$  relation appears to evolve, although this is primarily attributable to luminosity-limit selection effects. In order to probe intrinsic redshift evolution of sources in  $L_{\text{IR}} - T_{\text{dust}}$ , a larger dynamic range of luminosities is needed over narrow redshift ranges (e.g. expanding to  $> 10^{12-13}\ L_{\odot}$  sources at  $0.0 < z < 0.5$  would help greatly). In contrast to  $850\ \mu\text{m}$  selection,  $250\ \mu\text{m}$  selection is relatively unbiased with dust temperature (Casey *et al.* 2011).

There has been work which argues that the selection biases in  $L_{\text{IR}} - T_{\text{dust}}$  space are minor compared to physical effects (Sajina *et al.* 2007). The argument is that there is more intense dust heating in more extreme star forming environments. Our data support this, since the dust temperature bias effects are less prominent using SPIRE selection. Although selection effects play a role in our perceived relation, we fit dust temperature as a function of  $L_{\text{IR}}$  and find a significant correlation for SPIRE selected samples of  $\langle T_{\text{dust}} \rangle = 0.47^{+0.09}_{-0.06} (L_{\text{FIR}})^{0.144 \pm 0.006} [K L_{\odot}^{-1}]$ . The slope of this correlation, 0.14, is steeper than is seen in the local *IRAS* sample. We highlight that the difference between the two samples can be attributed to two factors. First, the dust temperature bias of the *IRAS* sample, selected at  $60\ \mu\text{m}$  with  $S_{60} > 5.24\ \text{Jy}$ , which selects against low dust temperature sources (see Figure 19, right). Second, the local sample is a single-redshift snapshot at  $z = 0$ , while our sample is spread over a wide epoch range,  $0 < z < 2$  (with 36 sources at  $2 < z < 5$ ). Fitting the whole sample together washes out any evolution in the  $L_{\text{IR}} - T_{\text{dust}}$  relation due to the strong redshift dependence of luminosity (e.g. Seymour *et al.* 2010). Eventually, much larger samples will make it possible to probe the  $L_{\text{IR}} - T_{\text{dust}}$  relation as a function of redshift.

#### 4.5. Comparison to SMGs and ‘missing’ warm-dust ULIRGs

Submillimetre Galaxies (SMGs) selected at 0.85–1.3 mm by SCUBA, LABOCA, AzTEC, or MAMBO have dominated the studies of high- $z$  starbursts for the past decade. While *Herschel*-selected galaxies overlap with the SMG population (Roseboom *et al.* 2012), the correspondence between source detectability at 250–500  $\mu\text{m}$  and  $\sim 850\ \mu\text{m}$  is not obvious. Although *Herschel* detects galaxies at their SED peak at  $z \sim 1 - 2$  (and is more sensitive to lower luminosities at  $z < 2$  than

SCUBA), the submm has the advantage of preferentially detecting higher-redshift galaxies and detecting them to lower luminosity limits than *Herschel*.

Unfortunately, very few of our SPIRE galaxies were directly observed with SCUBA, LABOCA, AzTEC or MAMBO on account of small survey areas for those instruments, so it is difficult to assess population overlap directly. However, using the SED fits from § 4.2, we can estimate  $850\ \mu\text{m}$  flux densities for every HSG. These SED-predicted  $850\ \mu\text{m}$  flux densities span a wide range, from  $\sim 0.2$ – $30\ \text{mJy}$ . Figure 20 shows the relation between fitted dust temperature and extrapolated  $850\ \mu\text{m}$  flux density for SPIRE galaxies; there is a clear relation between dust temperature and  $850\ \mu\text{m}$ -detectability.

We infer that  $79^{+4}_{-8}\%$  of all SPIRE galaxies are *undetectable* at  $850\ \mu\text{m}$  at a flux cut-off of  $S_{850} < 5\ \text{mJy}$ . Even considering a submillimeter detection threshold as low as  $2\ \text{mJy}$  (the lowest  $3\sigma$  detection limit for SCUBA, which had a confusion noise of  $\sim 0.7\ \text{mJy}$  at  $850\ \mu\text{m}$  Blain *et al.* 1999),  $47^{+27}_{-14}\%$  of SPIRE galaxies would be undetectable at  $850\ \mu\text{m}$ . While this is a large fraction, it could be that most of these are at low redshift, and therefore low luminosities and low SFRs. The ‘missing’ fraction as a function of redshift is plotted on the right panel of Figure 20. Indeed the fraction of HSGs not detectable at  $850\ \mu\text{m}$  is high at  $z < 1$ ,  $83^{+4}_{-7}\%$ , yet even at higher redshifts,  $1 < z < 2$ , the fraction is substantial:  $72^{+5}_{-11}\%$  of HSGs have  $S_{850} < 5\ \text{mJy}$ .

The fact that  $850\ \mu\text{m}$  selection misses a large fraction of infrared-bright starbursts is not new, but has been difficult to measure directly or estimate in the past. This dust temperature selection effect was studied in detail in the pre-*Herschel* era (Blain *et al.* 2004; Chapman *et al.* 2004; Casey *et al.* 2009, 2011,?) where conservative estimates of the ‘missing’ warm-dust ULIRG population (often referred to as ‘OFRGs’ or Submillimeter-Faint Radio Galaxies, ‘SFRGs’) were on the order of 10–20%, and later works went on to estimate the missing fraction at  $\gtrsim 30\%$  using photometric data and limited spectroscopic data from *Herschel* (Chapman *et al.* 2010; Magdis *et al.* 2010).

While we note that roughly half of SPIRE galaxies are below the detection threshold at  $850\ \mu\text{m}$ , we can also investigate the converse statistic. How many SMGs are not detectable by SPIRE? We use the original sample of SMGs described in Chapman *et al.* (2005), along with assumed IR luminosities estimated via the FIR/radio correlation to fit SEDs and extrapolate to SPIRE fluxes. We then use these hypothetical fluxes to calculate a SPIRE detectability, in other words, we determine what fraction of the SMGs would pass our  $>3\sigma$  selection criteria. The percentage of SMGs which are 250–500  $\mu\text{m}$  detectable is shown at bottom on the right panel of Figure 20. At  $z < 2$ , all SMGs are detected with SPIRE, but above  $z > 2$ , anywhere from 20% to 60% of SMGs are SPIRE dropouts.

We also investigate this fraction using real SPIRE coverage of SMG fields together with LHN data presented in Chapman *et al.* (2010) and SPIRE coverage around SMGs from Chapman *et al.* (2005). The statistic is consistent, roughly 1/3 of SMGs are not detected in SPIRE, and nearly all at  $z > 2.5$ . Since the sample size of SMGs with overlapping SPIRE data is about half the size of the

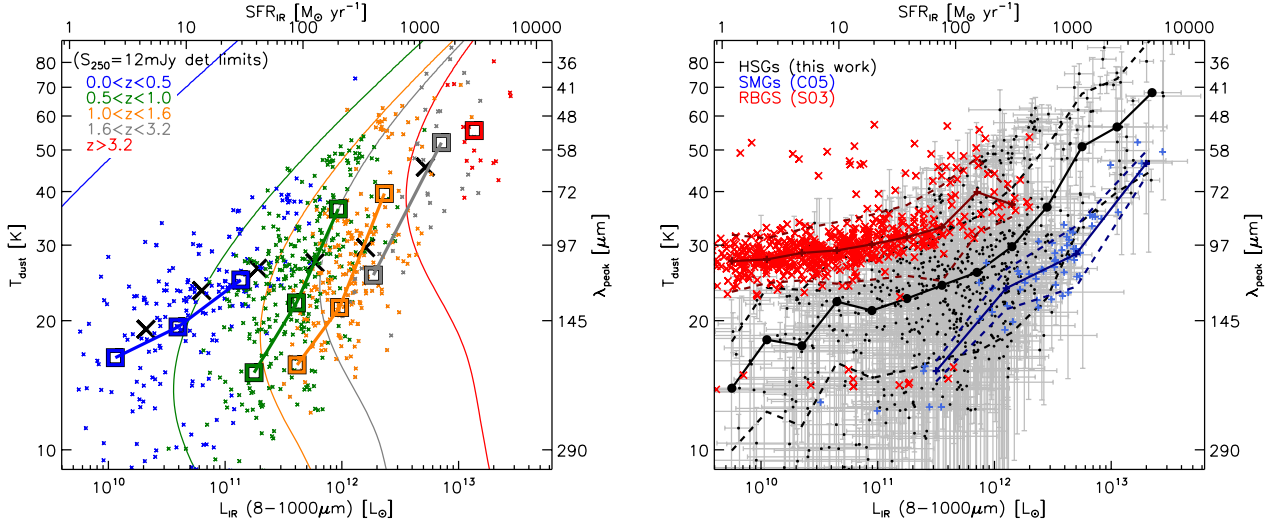

FIG. 19.—  $L_{\text{IR}}$  against  $T_{\text{dust}}$  as an indicator of the variation of SED type in our sample. Dust temperature is estimated via Wien's Law (inversely proportional to peak of the SED). Colors on the left denote redshift bins, and the mean  $L_{\text{IR}} - T_{\text{dust}}$  relation for each redshift slice is shown as large squares. This relation changes with increasing redshift, however this can be attributable to the selection bias of SPIRE selection: the  $250\mu\text{m}$  detection limits at fixed redshifts are shown as solid lines, whose color corresponds to the lower redshift limit of the bin. At a fixed temperature, only sources to the right of the line (i.e. at higher luminosities) are detectable. The mean luminosities and temperatures for the composite SEDs in Figure 18 are large crosses. At right, we illustrate the  $L_{\text{IR}} - T_{\text{dust}}$  relation for SPIRE galaxies (black) in comparison to local *IRAS* galaxies, from the RBGS and GOALS samples (red; Sanders *et al.* 2003; Armus *et al.* 2009), and SMGs (blue; Chapman *et al.* 2005; Pope *et al.* 2006). We refit SEDs for all samples consistently so that both dust temperatures and luminosities are directly comparable. This demonstrates that our SPIRE galaxy sample is statistically colder than local *IRAS* galaxies of similar luminosities but warmer than SMGs of similar luminosities. Although we observe a different slope to the  $L_{\text{IR}} - T_{\text{dust}}$  relation than is seen locally, our sample is not large enough to measure evolution, since luminosity is largely a function of redshift (e.g. Seymour *et al.* 2010).

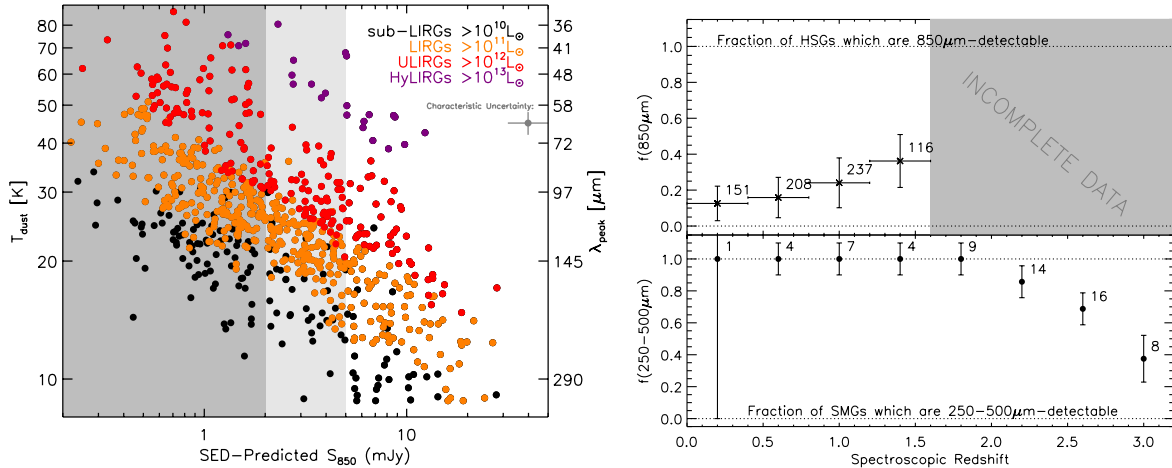

FIG. 20.— Predicted  $850\mu\text{m}$  flux densities for our SPIRE sample against the fitted SED dust temperatures. The characteristic uncertainty in either measurement is shown in the upper right. Note that the classic SMG selection criteria,  $S_{850} > 5\text{mJy}$  would exclude  $79^{+4}_{-8}\%$  of SPIRE sources from detection in traditional  $850\mu\text{m}$ -based SMG surveys:  $83^{+4}_{-7}\%$  of HSGs at  $z < 1$  and  $72^{+5}_{-11}\%$  of HSGs at  $1 < z < 2$ . This is significantly higher than previous estimates to the ‘missing’ fraction of warm-dust ULIRGs at  $z > 1$  missed by SMG surveys. At right, we show the fraction of SPIRE galaxies which are  $850\mu\text{m}$ -detectable and  $850\mu\text{m}$ -selected SMGs which are SPIRE-detectable, as a function of redshift. Here SPIRE detectability is defined as  $S_{250}, S_{350}$  or  $S_{500} > 12\text{mJy}$ , and qualification as an SMG is  $S_{850} > 5\text{mJy}$ . This illustrates that 60-80% of SPIRE galaxies are undetectable at  $850\mu\text{m}$  out to  $z \sim 1.6$ , and that SMGs are only expected to drop out of the SPIRE bands at  $z > 2$  for 20-60% of sources. The numbers next to each point represents the number of galaxies used in each bin. There are too few SPIRE galaxies to reliably determine this statistic at  $z > 1.6$  (gray shaded region).

FIG. 21.— Ratio between FIR luminosity and radio luminosity in our sample,  $q_{\text{IR}}$ , against redshift. We compare against the moderate evolution measured by Ivison *et al.* (2010)  $\propto (1+z)^{-0.26 \pm 0.07}$  (gray band). We measure slightly stronger evolution,  $q_{\text{IR}} \propto (1+z)^{-0.30}$ .

full SMG sample, we use the extrapolated flux densities in Figure 20.

#### 4.6. The FIR/Radio Correlation

Since IR luminosities were derived independently of radio luminosity, we measure the FIR/radio ratio,  $q_{\text{IR}}$ , for radio-detected HSGs in order to assess the FIR/radio correlation for starbursts (see Helou, Soifer & Rowan-Robinson 1985; Condon 1992; Ivison *et al.* 2010,?) for HSGs. We use the bolometric  $q_{\text{IR}}$  ratio between 8–1000  $\mu\text{m}$  flux and 1.4 GHz radio flux as defined in Ivison *et al.* (2010), with IR luminosities measured from rest-frame 8  $\mu\text{m}$  to 1000  $\mu\text{m}$ . Figure 21 shows the  $q_{\text{IR}}$  ratio evolving with redshift for synchrotron slope  $\alpha = 0.75$ , where  $S_\nu \propto \nu^{-\alpha}$ . Our sample is consistent with the moderate evolution measured by Ivison *et al.* (2010,?) and Magnelli *et al.* (2010). We measure  $q_{\text{IR}} \propto (1+z)^\gamma$  where  $\gamma = -0.30 \pm 0.02$  using only the  $0 < z < 2$  HSG sample (an independent assessment of the  $z > 2$  sample is given in C12). Ivison *et al.* (2010) measured  $\gamma = -0.04 \pm 0.03$  at  $z = 0-2$ , but found that their  $z < 0.5$  samples contaminated this measurement since they were few in number and not well matched in luminosity to the higher redshift sources; they measure  $\gamma = -0.26 \pm 0.07$  for the  $0.5 < z < 2.0$  sample, which is consistent with our finding,  $\gamma = -0.30$ . Either with or without our  $z < 0.5$  sample, we measure  $\gamma = -0.30$ , likely because our sample is dominated (68%) by sources at  $0.5 < z < 1.5$ . Note that the evolution we measure is much more pronounced if the original luminosity limits defining  $S_{\text{FIR}}$  are used, 40–120  $\mu\text{m}$ :  $q_{\text{FIR}} \propto (1+z)^{-0.59 \pm 0.04}$ . Note also that the significantly limiting factor of this measurement is that our sample is partially radio-selected and is not a luminosity-matched sample.

## 5. DISCUSSION

The characterization of galaxies by *Herschel* is the largest advance in understanding star formation in the infrared since the discovery of SMGs by SCUBA. This

paper has presented a spectroscopic survey of 1594 SPIRE sources, 767 have identified spectroscopic redshifts from  $0 < z < 5$ , and 731 at  $z < 2$ . Securing spectroscopic redshifts is itself very valuable for follow-up studies of this population, from their metallicities, stellar populations, morphologies and evolutionary histories to their molecular gas properties and dust content. However, arguably the impact of this population on the cosmic star formation rate density (SFRD) is the most relevant computation for galaxy formation and evolution studies in general. The luminosity function has only ever been measured in integrated IR luminosity ( $L_{\text{IR}}(8-1000 \mu\text{m})$ ) for limited populations of SMGs with known incompleteness (Chapman *et al.* 2005; Wardlow *et al.* 2011) or from extrapolations to the IR from *Spitzer* (Le Floc'h *et al.* 2005; Caputi *et al.* 2007; Magnelli *et al.* 2011) making use of model templates or explicitly assuming SEDs from libraries (Le Borgne *et al.* 2009; Béthermin *et al.* 2011; Marsden *et al.* 2011). This section presents the integrated IR luminosity function of *Herschel* galaxies, a discussion of the completeness of our samples, the implications for the cosmic SFRD and comparisons to these previous studies.

### 5.1. Luminosity Function

We compute the integrated IR (8–1000  $\mu\text{m}$ ) luminosity functions (LFs) of SPIRE-detected galaxies in four redshift bins where the spectroscopic completeness is constrained and the number of identifications is  $\sim 100$  per bin:  $0.0 < z < 0.4$ ,  $0.4 < z < 0.8$ ,  $0.8 < z < 1.2$ , and  $1.2 < z < 1.6$ . We use the  $1/V_{\text{max}}$  accessible volume technique where

$$\Phi_z(L)\Delta L = \sum_{i=0}^n \frac{1}{V_i(L)} \quad (2)$$

$\Phi_z(L)$  is given in units of  $h^3 \text{Mpc}^{-3} \log L^{-1}$  and  $\Phi_z(L)\Delta L$  is the number density of sources with luminosities between  $L$  and  $L + \Delta L$ . Here  $V_i(L)$  is the comoving volume within which the  $i$ th source is detectable in our survey. This accessible volume is determined by constructing a detection limit in  $L_{\text{IR}}-z$  space for each source. As was evident in Figure 16, the SPIRE detection limit is highly dependent on dust temperature (i.e. 40 K galaxies will have a different  $L_{\text{IR}}-z$  detection threshold than 20 K galaxies). The luminosity limit per source is determined by assuming an SED (of type given by Eq 1) with fitted  $T_{\text{dust}}$ , and the  $3\sigma$  detection bounds at 250  $\mu\text{m}$ , 350  $\mu\text{m}$ , and 500  $\mu\text{m}$ , where the lowest luminosity limit with redshift is adopted for the accessible volume calculation. The measured luminosity function, after correction for spectroscopic incompleteness (as discussed earlier in the text and shown in Figure 12), is given in Table 1 and shown in Figure 22 as filled, colored circles.

As a check, we also compute the luminosity functions for the same XID selection using the photometric redshifts in COSMOS (Ilbert *et al.* 2010) and the same luminosity limit technique (for  $\sim 6000$  sources over  $\sim 2.2 \text{deg}^2$ ). The photometric redshift results are shown on Figure 22 as open gray squares. Within uncertainties, the spectroscopic and photometric luminosity functions agree at each epoch.

Figure 22 clearly demonstrates evolution in the luminosity function with redshift, with ultraluminous

FIG. 22.— Evolving luminosity functions for our HSG spectroscopic sample. The redshift bins are  $0.0 < z < 0.4$  (purple),  $0.4 < z < 0.8$  (red),  $0.8 < z < 1.2$  (yellow) and  $1.2 < z < 1.6$  (green). We also include the estimated luminosity functions from photometric redshifts in COSMOS (Ilbert *et al.* 2010) as gray boxes and associated uncertainties. The best-fit Schechter functions are shown as dotted colored lines, with associated uncertainties (shaded regions) based on uncertainty in  $\alpha$ ,  $\Phi^*$  and  $L^*$ . The lower luminosity completeness limits of each bin are shown as dashed vertical lines. Below these luminosities, our SPIRE samples are incomplete (in terms of SPIRE detectability). Note that these luminosity functions are corrected for spectroscopic incompleteness (as detailed in Figure 12).

( $>10^{12} L_{\odot}$ ) and hyperluminous ( $>10^{13} L_{\odot}$ ) galaxies becoming far more abundant with increasing  $z$  than in the local Universe. At each of the four epochs, we fit Schechter functions of the form  $\Phi = \Phi^* x^{\alpha} e^{-x}$ , where  $x = L/L^*$ . The faint end of the luminosity function, dominated by the  $x^{\alpha}$  power law, is largely unprobed by our dataset since  $L^*$ , the turnover luminosity, is approximately equal to the lower luminosity limit of SPIRE in each bin. Without constraints, we decided to fix  $\alpha = -0.35$ , our measurement from the local RBGS sample (Sanders *et al.* 2003) and the  $0 < z < 0.4$  photometric redshift sample, which is also consistent with prior local and high- $z$  measurements (Le Floc'h *et al.* 2005; Caputi *et al.* 2007). We add a large margin of uncertainty on the slope  $\alpha$ , since its impact on integrated star formation density increases with redshift ( $\sigma_{\alpha} = 0.1$  at  $z \approx 0$ , increasing to 0.5 at  $z \approx 1.4$ ). At the top end of the luminosity function, we note slight excesses at  $0.0 < z < 0.4$ ,  $0.4 < z < 0.8$  and  $0.8 < z < 1.2$ , which, in other samples, has been attributed to AGN contributions to in-

frared luminosity; while a double power law luminosity function might provide an alternate fitting method, the difference in this work is inconsequential considering the uncertainty on the luminosity function points themselves.

The parameters  $\Phi^*$  and  $L^*$  are then varied to provide an optimal fit to data at each epoch. We measure evolution in both parameters, as given in Table 1. However, it should be stressed that the measurement of these parameters' values is highly degenerate with variation in the faint end slope,  $\alpha$  and with each other. Much larger data sets, particularly those which constrain the faint end slope via stacking techniques, are needed for detailed analysis on the evolution of  $\Phi^*$  and  $L^*$ . This detailed work is being done with larger samples from COSMOS (M. Vaccari, E. Le Floc'h, private communication).

## 5.2. Star Formation Rate Density

To estimate the contribution of SPIRE-detected sources to the cosmic star formation rate density (SFRD), our measured luminosity functions are converted to SFR func-

NOTE. — The luminosities in this table are integrated within 8–1000  $\mu$ m. They represent the central luminosity of sources in each bin, in other words, the bin for luminosity  $L$  covers sources with luminosities between  $L - \Delta L/2$  and  $L + \Delta L/2$ . The luminosity functions in this table are based exclusively on our SPIRE galaxy spectroscopic sample. We compute the luminosity function in units of  $\text{h}^3 \text{Mpc}^{-3} \log L^{-1}$ .

tions via the Kennicutt (1998) prescription assuming a non-evolving Salpeter IMF. Note that there is some recent discussion, particularly in relation to very high luminosity sources at  $z > 2$ , that the Kennicutt conversion from infrared luminosity to SFR might not hold due to IMF variation (Swinbank *et al.* 2008); however, in this paper we use it for consistency with previous work on the infrared SFRD (Le Floc’h *et al.* 2005; Hopkins & Beacom 2006; Caputi *et al.* 2007; Magnelli *et al.* 2011).

The SFRD contribution from HSGs is shown in Figure 23. The left panel shows the raw conversion of the luminosity function data points to SFRD contribution, including all sources above and below the completeness luminosity limit (dashed lines on Figure 22), and without extrapolation to lower or higher luminosities. Although we excluded  $1.6 < z < 2.0$  sources from the luminosity function calculation due to small numbers, we bring them back for this computation. The measured HSG SFRD appears to increase from  $z = 0$  to  $z = 1$ , and then fall sharply at  $z = 1.5$ ; however, this is due entirely to the luminosity limits of the sample at the given epochs. For example, the highest redshift bin,  $z \approx 1.8$ , has a lower luminosity limit of  $\log L_{\text{IR}} = 12.3$ , significantly higher than the lower redshift bins. Similar luminosity limit restrictions exist for the literature values of the SFRD found from SMGs, in Chapman *et al.* (2005), Wall, Pope & Scott (2008) and Wardlow *et al.* (2011).

Although SMGs are thought of as a very rare class

of galaxy in this context, it is important to point out that this depends entirely on the adopted definition of ‘SMG’ and associated luminosity limits. The  $\sim 1$  dex difference between the SFRD contributions of 850  $\mu$ m-selected SMGs and 250–500  $\mu$ m-selected HSGs at  $z \sim 1$  is due to the effective luminosity limits of SPIRE or 850  $\mu$ m selection (where HSG selection probes luminosities  $\sim 5$  times fainter) and also due to the dust temperature bias of 850  $\mu$ m-selection (another factor of  $\sim 2$ ).

Drawing a fair comparison with other samples requires interpolation in the luminosity function across equal luminosity bins via our best-fit Schechter functions. Several literature sources have estimated the total integrated star formation rate density from infrared sources using a variety of datasets: *Spitzer*-24  $\mu$ m-identified sources in COSMOS (Le Floc’h *et al.* 2005); *Spitzer*-24  $\mu$ m sources in both GOODS fields (Caputi *et al.* 2007; Magnelli *et al.* 2011); and *Akari*-selected sources (Goto *et al.* 2010). We also draw on the full optical and ultraviolet data compilation of Hopkins & Beacom (2006), which is extinction corrected to account for infrared emission in optically-bright galaxies. On the right panel of Figure 23, we show the breakdown of the SFRD in 1 dex luminosity bins,  $< 10^{11} L_{\odot}$  (sub-LIRGs),  $10^{11} < z < 10^{12} L_{\odot}$  (LIRGs),  $10^{12} < z < 10^{13} L_{\odot}$  (ULIRGs), and total integrated infrared. On a whole, we observe the same trends as other literature works: the total integrated infrared SFRD contribution is comparable to the total optical and ultraviolet contribution (i.e. just as much star formation is obscured as is unobscured) LIRGs dominate at  $z \approx 1$ , and ULIRGs become increasingly important at  $z > 1$ . However, a few subtle differences stand out. For example, both Le Floc’h *et al.* (2005) and Caputi *et al.* (2007) find higher contributions from ULIRGs at  $z < 0.5$  than is measured in the Magnelli *et al.* (2011) sample or in our sample. Since both prior samples were 24  $\mu$ m-selected, this could be indicative of the disagreement between 24  $\mu$ m and total integrated luminosity. At  $z > 1$ , the Magnelli *et al.* (2011) sample shows a deficit in ULIRGs with respect to our sample (also seen in the models of Béthermin *et al.* 2011). While this deficit could be due to SED assumptions, it could also be due to cosmic variance and the size of the GOODS fields used in Magnelli *et al.* (e.g., as is known to be a problem in CDFS, which has a submm deficit, see Weiß *et al.* 2009).

The uncertainties on the SFRD measurements are dominated by the uncertainty in the faint-end slope of the luminosity function, which is not well constrained. At higher redshifts  $L^*$  increases; this impact of the faint-end slope uncertainty then grows, since sub-LIRGs and LIRGs are not constrained with our data beyond  $z > 1.2$ . This is not only true for our data set, but any data set (selected via 24  $\mu$ m or radio with a PACS or SPIRE detection) which does not employ stacking analysis to constrain faint sources. Further work is needed on stacking 24  $\mu$ m- and radio-selected samples of galaxies to probe fainter luminosities out to high redshifts over large areas of sky less prone to cosmic variance.

It is clear from this work that the importance of infrared-luminous star formation in the context of cosmic star formation is high, and equally high as rest-frame UV/optical estimates, even though prior surveys of SMGs seem to imply that infrared starbursts are rare even at  $z \sim 1$ –2. *Herschel*-SPIRE has enabled us to di-

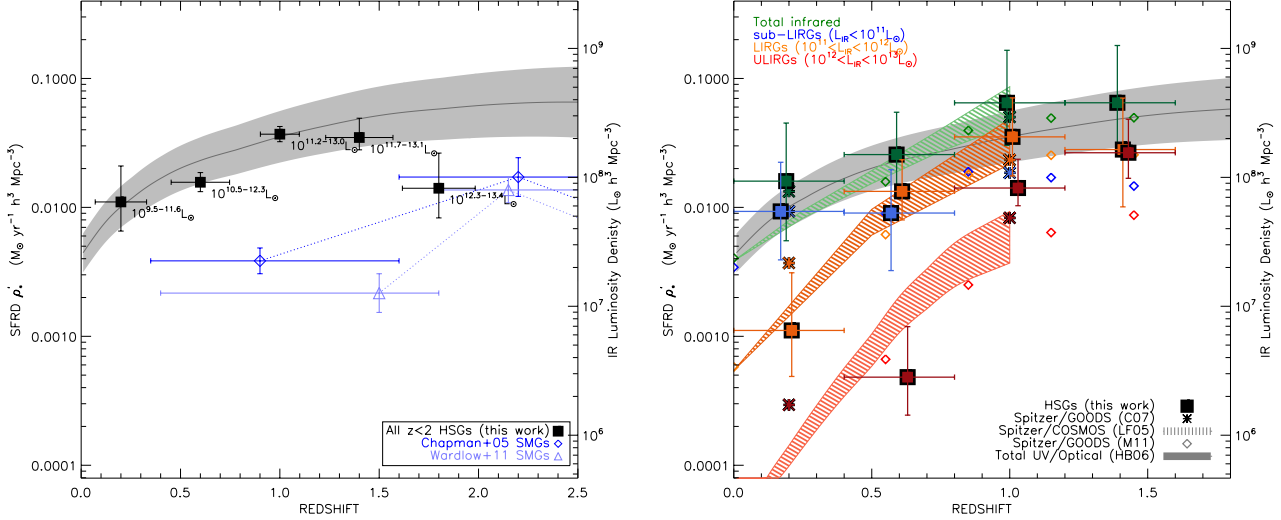

FIG. 23.— Contribution of SPIRE galaxies to the cosmic star formation rate density from  $z = 0$  to  $z = 2$ . We compare against the compilation in Hopkins & Beacom 2006 of optical/UV SFRD estimates which are dust-corrected (large grey area, representing the associated uncertainty of UV/optical estimates). We also overplot the SFRD points estimated by Chapman *et al.* (2005) and Wardlow *et al.* (2011) for SMGs which are substantially lower by  $\sim 10\times$  than the optical/UV dust-corrected SFRD and HSGs at  $z < 1.5$ . At left, we measure the SFRD from this spectroscopic sample by converting the measured luminosity functions to star formation rate functions, then integrating. At right, we use the best-fit Schechter functions in Figure 22 to extrapolate over luminosities not directly probed by our survey, to measure the total infrared (green), sub-LIRG (blue), LIRG (orange) and ULIRG (red) contributions to the SFRD (colors are consistent across different data sets). The right y-axes give the value of the IR luminosity density which translates directly to SFRD via the Kennicutt (1998) scaling. We gather similar computations from the literature for comparison: Le Floc'h *et al.* (2005) *Spitzer* samples in COSMOS (hashed regions), Caputi *et al.* (2007) *Spitzer* samples in GOODS (asterisks), and Magnelli *et al.* (2011) *Spitzer* samples in GOODS (diamonds).

rectly constrain the far-infrared unlike previous work in the area, extrapolating from  $24\mu\text{m}$ . Our observations confirm the importance of dust obscured star formation across the first 10 billion years of the Universe's history.

## 6. CONCLUSIONS

This paper has presented a large spectroscopic survey of galaxies selected in the *Herschel*-SPIRE 250–500  $\mu\text{m}$  bands and followed up spectroscopically on Keck LRIS and DEIMOS. Out of 1594 spectroscopic targets spanning  $0.93\text{ deg}^2$  in multiple deep legacy fields, 767 sources had identifiable redshifts from their rest-frame UV or optical spectra, 731 of which are at  $z < 2$ . We present the following conclusions:

- The redshift distribution of SPIRE-selected spectroscopically-confirmed galaxies peaks at  $z = 0.85$  and has a tail of sources extending out to  $z \approx 5$ . The vast majority of this spectroscopic sample ( $731/767 \approx 96\%$ ) is at  $z < 2$ , mostly spectrally identified by [OII], [OIII], H $\beta$ , or H $\alpha$  emission.
- Our spectroscopic sample excludes sources without  $24\mu\text{m}$  or radio 1.4 GHz counterparts. A negligible fraction of SPIRE-sources in deep legacy fields are thought to drop out in the mid-IR and radio at  $z < 2$ , meaning our SPIRE targeting is close to complete at  $z \lesssim 2$ .
- Only  $\sim 50\%$  of spectroscopic targets yield redshifts (767 with identifications, 826 without). Under photometric observing conditions,  $\sim 60\%$  yield identifications. We constrain the spectroscopic completeness at  $z < 2$  to 20–80%, depending on redshift, using large catalogs of photometric redshifts. The

sources without spectroscopic identifications either were observed in poor weather conditions, have no optical counterpart (i.e. no source picked up on the slit after 1–2 hrs integration), or have spectra not easily identified with a single redshift (e.g. continuum without emission or absorption features).

- We measure the accuracy of HSG optical/near-infrared photometric redshifts at  $\Delta z/(1 + z_{\text{spec}}) = 0.29$ , a factor of  $\sim 3$ –4 times worse than photometric redshifts for normal field galaxies. We determine that the lack of reliability in photometric redshifts for HSGs is due to more significant optical obscuration and higher overall star formation rates (thus higher line-to-continuum ratios). We caution that future analysis of aggregate properties of infrared-selected samples like HSGs might be biased by only making use of large photometric redshift catalogs.
- We observe a correlation between dust temperature and infrared luminosity which is partially a selection effect and partially thought to be physically real. The selection effect is caused by the dependence of SPIRE flux density on dust temperature and the physical motivation comes from the local observation that more luminous galaxies have more compact, clumpy and therefore hot dust.
- SPIRE color does not evolve with redshift in our spectroscopic sample, due to the redshift dependence of luminosity and the luminosity dependence on dust temperature (a combination of selection effects and physical mechanisms).
- We infer the aggregate properties of HSGs by combining the near-infrared to radio measurements by

selection method and luminosity. We find little difference between the bulk infrared properties of radio-selected galaxies and  $24\mu\text{m}$ -selected galaxies, and good overall agreement with the FIR/radio correlation. Consistent with our results from individual sources, we see an increase in dust temperature with luminosity in the composite IR SEDs. At luminosities  $>10^{12.5} L_{\odot}$ , we detect the  $\approx 10\mu\text{m}$  Si absorption feature in the composite, resembling the SED of the local ULIRG Arp 220.

- By extrapolating our infrared SED fits to  $850\mu\text{m}$ , we determine that only  $79^{+4}_{-8}\%$  of HSGs would be detectable as ‘classic’ SMGs ( $S_{850} > 5\text{ mJy}$ ). This fraction is highest at low redshift,  $83^{+4}_{-7}\%$  at  $z < 1$ , and still significant,  $72^{+5}_{-11}\%$ , from  $1 < z < 2$ .
- For the 331 radio-selected sources with spectroscopic confirmations, we measure the evolution in the FIR/radio correlation and find  $q_{\text{IR}} = (1 + z)^{-0.30 \pm 0.02}$ . This evolution is stronger than some previous measurements, however the sample is biased by being radio-detected, thus the intrinsic evolution of  $q_{\text{IR}}$  with redshift is likely to be shallower.
- We compute the luminosity functions for HSGs in four redshift bins across  $0 < z < 1.6$  and find agreement with predictions from photometric redshifts. The luminosity functions are well-fit by Schechter functions, with evolving parameters  $\Phi^*$  ( $3.2 \times 10^3 h^3 \text{Mpc}^{-3}$  at  $z = 0.2$  to  $3.1 \times 10^{-4} h^3 \text{Mpc}^{-3}$  at  $z = 1.4$ ) and  $L^*$  ( $5 \times 10^{10} L_{\odot}$  at  $z = 0.2$  to  $2 \times 10^{12} L_{\odot}$  at  $z = 1.4$ ). The faint-end of the luminosity function is not well probed by our data and would only be accessible from *Herschel* data through stacking analyses.
- We find the HSG contribution to the cosmic star formation rate density to be substantial at  $z < 2$ , essentially comparable to the star formation rate density from optical/near-IR surveys  $\gtrsim 1 \times 10^{-2} M_{\odot} \text{yr}^{-1} h^3 \text{Mpc}^{-3}$ . Without relying on extrapolations from the mid-infrared or model template libraries, we measure the contribution from LIRGs ( $10^{11} < L < 10^{12} L_{\odot}$ ) to the SFRD peaks at  $z \sim 1$ , and the ULIRG ( $> 10^{12} L_{\odot}$ ) contribution increases with  $z$ , nearly surpassing the LIRG contribution at  $z \sim 1.4$ .

This work has demonstrated that infrared-luminous galaxies form an integral part of galaxy formation across a wide range of epochs, particularly at  $0 < z < 2$ . With spectroscopic redshifts in hand, follow-up studies can be

more efficiently carried out to determine the *physical* and *evolutionary* origins of HSGs as a function of infrared luminosity, dust temperature, dust mass, and AGN content. This work will then begin to shed light on the dominant mechanisms producing obscured star formation in the Universe.

#### ACKNOWLEDGEMENTS

We thank the anonymous reviewer for a very useful, constructive report which improved the manuscript. CMC is generously supported by a Hubble Fellowship from Space Telescope Science Institute, grant HST-HF-51268.01-A. The data presented herein were obtained at the W.M. Keck Observatory, which is operated as a scientific partnership among the California Institute of Technology, the University of California and the National Aeronautics and Space Administration. The Observatory was made possible by the generous financial support of the W.M. Keck Foundation. The authors wish to recognize and acknowledge the very significant cultural role and reverence that the summit of Mauna Kea has always had within the indigenous Hawaiian community. We are most fortunate to have the opportunity to conduct observations from this mountain. This work would not be possible without the hard work and dedication of the Keck Observatory night and day staff; special thanks to Marc Kassis, Luca Rizzi and Greg Wirth for help and advice while observing. The analysis pipeline used to reduce the DEIMOS data was developed at UC Berkeley with support from NSF grant AST-0071048. Thanks to Nick Scoville and Brian Siana for useful discussions which improved the paper.

SPIRE has been developed by a consortium of institutes led by Cardiff Univ. (UK) and including: Univ. Lethbridge (Canada); NAOC (China); CEA, LAM (France); IFSI, Univ. Padua (Italy); IAC (Spain); Stockholm Observatory (Sweden); Imperial College London, RAL, UCL-MSSL, UKATC, Univ. Sussex (UK); and Caltech, JPL, NHSC, Univ. Colorado (USA). This development has been supported by national funding agencies: CSA (Canada); NAOC (China); CEA, CNES, CNRS (France); ASI (Italy); MCINN (Spain); SNSB (Sweden); STFC, UKSA (UK); and NASA (USA).

This research has made use of data from the HerMES project (<http://hermes.sussex.ac.uk/>). HerMES is a *Herschel* Key Programme utilizing Guaranteed Time from the SPIRE instrument team, ESAC scientists and a mission scientist. HerMES is described in Oliver *et al.* (2012). The SPIRE data presented in this paper will be released through the HerMES Database in Marseille, HeDaM (<http://hedam.oamp.fr/HerMES>).

NOTE. — Source names indicate both detection band in the XID catalog (24 $\mu\text{m}$  or 1.4 GHz) and source position based on near-infrared/optical counterparts. Asterisks after the name indicate the source was observed in near-photometric conditions. Superscripts in the  $z_{\text{spec}}$  column indicate the instrument with which observations were obtained, LRIS (L) or DEIMOS (D). The CONF column indicates the confidence in the spectroscopic redshift identification, and ranges here from 1 to 5, 5 being the most confident (further identifications at CONF<1 have been excluded from this paper). Photometric redshift superscript indicates which field the data are in, UDS (U), CDFS (S), COSMOS (C), LHN (L), GOODS-N (G), or Elais-N1 (E). PACS flux densities come from PEP (Lutz *et al.* 2011) in COSMOS and from HerMES (Oliver *et al.* 2012) in LHN. Ellipsis (...) denote that the given source is undetected at the corresponding wavelength or has no photometric redshift despite having the necessary imaging or coverage whereas dashes (–) denote that no data exist.
