36 **Summary**

37 ● Nutrient-distribution and neighbours can impact plant growth, but how
38 neighbours shape root foraging strategy for nutrients is unclear. Here, we explore
39 new patterns of plant foraging for nutrients as affected by neighbours to improve
40 nutrient-acquisition.

41 ● Maize (*Zea mays*) was grown alone (maize), or with maize (maize/maize) or faba
42 bean (*Vicia faba*) (maize/faba bean) as a neighbour on one side and with or
43 without phosphorus (P)-rich zone on the other in a rhizo-box experiment.

44 ● Maize demonstrated root avoidance in maize/maize, with reduced root-growth in
45 ‘shared’ soil, and increased growth away from its neighbours. Inversely, maize
46 proliferated roots in the proximity of neighbouring faba bean roots that had
47 greater P availability in the rhizosphere (due to citrate and acid phosphatase
48 exudation) than maize roots. Maize proliferated more roots, but spent less time to
49 reach, and grow out of, the P-patches away from neighbours in maize/maize than
50 maize/faba bean. Maize shoot-biomass and P uptake were greater in the
51 heterogeneous P treatment with maize/faba bean than maize/maize.

52 ● The foraging strategy of maize roots is an integrated function of heterogeneous
53 distribution of nutrients and neighbouring plants, consequently improving
54 nutrient acquisition and maize growth. Understanding the foraging patterns is
55 critical for optimizing nutrient management in crops.

56 **Keywords:** root foraging, nutrient heterogeneity, root-root interactions, phosphorus
57 acquisition, nutrient-use efficiency, *Zea mays* (maize).

58 **Introduction**

59 Plants experience significant challenges in obtaining nutrients as a result of spatial
60 variation in the distribution of soil nutrients and neighbours (Callaway *et al.*, 2003;
61 Cahill *et al.*, 2010; Cahill & McNickle, 2011). Consistent with a general
62 understanding of dynamic foraging behaviour in many animal species (Charnov,
63 1976; Krebs *et al.*, 1977), plants can detect and respond to variations in nutrient
64 availability and distribution in the soil environment (Kelly, 1990; Karban, 2008;
65 McNickle *et al.*, 2015). For example, when encountering a nutrient-rich patch, some
66 species invest resources into proliferating roots, particularly increasing the proportion
67 of fine roots (Drew, 1975; Hodge, 2004; Jing *et al.*, 2010). In addition to changing
68 root distributions in response to localized nutrient supply, plants can also modify
69 nutrient uptake kinetics (Jackson *et al.*, 1990). As root foraging is an active process
70 involving search for nutrients, plants invest more resources into highly enriched
71 patches than they do in homogeneous environments (McNickle & Cahill, 2009; Karst
72 *et al.*, 2012). Collectively, these root-foraging responses can significantly affect
73 nutrient acquisition as well as plant growth and yield (Hodge, 2004; Cahill &
74 McNickle, 2011).

75 The nutrient uptake benefits of root growth in a particular soil volume depend not
76 only on nutrient concentration, but also on occupancy patterns of neighbours (Cahill
77 *et al.*, 2010). Studies are increasingly finding that plants have highly varied nutrient
78 acquisition responses to the presence of neighbour roots (Semchenko *et al.*, 2007;
79 Mommer *et al.*, 2012; Abakumova *et al.*, 2016; Zhang *et al.*, 2016), with some
80 studied species demonstrating avoidance (i.e. roots growing away from the neighbour)
81 (Gersani *et al.*, 1998; Schenk *et al.*, 1999), and some species tending to grow roots
82 near neighbour roots (aggregation) (Maina *et al.*, 2002; de Kroon, 2007). Despite the
83 fact that nutrient depletion (Gersani *et al.*, 1998; Schenk, 2006) and root exudates
84 (Semchenko *et al.*, 2014) can trigger different responses in root-root interactions,
85 plant growth is mainly determined by soil nutrient availability; hence, adaptations that
86 allow plants to acquire nutrients efficiently in the presence of neighbours can strongly

87 influence plant performance (Cahill & McNickle, 2011; Padilla *et al.*, 2013). The
88 dynamics of root foraging patterns for heterogeneously-distributed nutrients by
89 individual plants are typically influenced by the co-occurring plants (Cahill *et al.*,
90 2010; Mommer *et al.*, 2012; Zhang *et al.*, 2016). Nonetheless, it remains unclear how
91 plants integrate the information on nutrient and neighbour distributions in their
92 foraging response that influences nutrient acquisition, plant growth, crop yield and
93 even the outcome of ecological interactions.

94 Maize production is essential to food security in China and throughout the world.
95 Because phosphorus (P) is poorly available in soils due to slow diffusion and strong
96 fixation (Hinsinger, 2001; Shen *et al.*, 2011), low P-use efficiency is one of the main
97 factors that limit maize yield. Maize/faba bean intercropping is widely adopted in
98 Chinese farming systems, particularly in northwest China, and is a good example of
99 cropping systems that enhance P-use efficiency and deliver yield advantages (Zhang
100 *et al.*, 2004, 2010; Li *et al.*, 2007, 2014a; Shen *et al.*, 2013). In the maize/faba bean,
101 maize roots spread underneath faba bean roots and showed greater compatibility of
102 the spatial root distribution between the intercropped maize and faba bean in
103 comparison to the maize/maize monocropping (Li *et al.*, 2006). Whilst some of the
104 maize crop yield and P uptake benefits from root proliferation in localized
105 (heterogeneously-supplied) nutrients zone are understood (Jing *et al.*, 2010, 2012; Ma
106 *et al.*, 2013; Shen *et al.*, 2013; Li *et al.*, 2014b), there is a considerable potential to
107 improve maize yield and/or nutrient-use efficiency through understanding the
108 integrated effects of patchy nutrient distribution and the neighbour species on maize
109 root foraging behaviours.

110 In order to test how neighbouring plants modify maize-root foraging for
111 heterogeneously-distributed P, and to understand the resulting impacts on P uptake
112 and maize productivity, we conducted a rhizo-box study with varying neighbour
113 species and soil P supply patterns. Specifically, we aimed to test the hypothesis: (1)
114 root foraging strategy is an integrated function of nutrient distribution and neighbour
115 species. The maize shows the specific root placement pattern in response to
116 neighbouring faba bean compared with neighbouring maize, consequently causing the

117 varied root P foraging strategies in P-rich patches, such as root proliferation, and the
118 time maize roots spend on acquiring heterogeneously-supplied P; and (2) the maize P
119 nutrition is governed by modified root foraging behaviours influenced by the
120 neighbour species and heterogeneously-supplied P.

121 **Materials and Methods**

122 **Experimental set-up**

123 We constructed plastic rhizo-boxes 40 cm long, 12 cm wide and 30 cm deep (Fig. 1a,
124 also refer to McNickle & Cahill, 2009) and the target maize was planted in the center
125 of the rhizo-box. Such a planting design was based on the previous field experiment
126 in that maize roots were concentrated mainly in the top 30 cm of soil, and
127 nutrient-rich patches were located 4-10 cm (we used 8 cm in the present study) away
128 from the maize plants (Jing *et al.*, 2010; Ma *et al.*, 2013; Zhang *et al.*, 2019). In the
129 rhizo-box experiment, one side (40 cm long and 30 cm deep) of the rhizo-box was
130 removable for ease of soil and root sampling. A single clear acrylic tube (6 cm in
131 diameter) was inserted horizontally 10 cm below the top edge of the rhizo-box (Fig.
132 1a). A minirhizotron camera (Bartz Technology Corporation, Santa Barbara, CA,
133 USA) was used to take images of roots during the experiment, enabling us to track
134 root growth along the tube.

135 The soil was collected from Shangzhuang experimental station of China
136 Agricultural University (latitude: 40° 14' N, longitude: 116°19' E) in Beijing, China,
137 air-dried and sieved through a 2-mm sieve. The soil contained (per kg) 11.5 g organic
138 carbon, 0.72 g total N, 8.5 mg available N ($\text{NO}_3^- + \text{NH}_4^+$), 2.6 mg NaHCO_3 -extractable
139 P, 32 mg NH_4Ac -extractable K, and had pH of 8.2 (the ratio of soil to 0.01 M CaCl_2
140 solution was 1:2.5). Before the treatments were established, basal nutrients in solution
141 were uniformly added to the soil at the following rates (mg per rhizo-box containing
142 15 kg soil): $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, 16,870; K_2SO_4 , 2000; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 650; Fe-EDTA,
143 87.8; $\text{MnSO}_4 \cdot \text{H}_2\text{O}$, 100; $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, 150; $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, 30; H_3BO_3 , 10; and
144 $\text{Na}_2\text{MoO}_4 \cdot 5\text{H}_2\text{O}$, 2.5.

145 There were six treatment combinations of soil P supply patterns (homogeneous or
146 heterogeneous) and maize planting treatments (alone, with neighbouring maize or
147 with faba bean) (Fig. 1b). Each treatment had six replicates. The amount of P (applied
148 as $\text{Ca}(\text{H}_2\text{PO}_4)_2 \cdot \text{H}_2\text{O}$) was the same in all treatments, but varied in spatial distribution:
149 (1) 525 mg P mixed evenly throughout the soil, resulting in 35 mg P kg^{-1} soil
150 (homogeneous treatment); (2) 255 mg P concentrated in a single rectangular column
151 ($4 \text{ cm} \times 12 \text{ cm} \times 30 \text{ cm}$, 1.5 kg soil, spanned the width and depth of each rhizo-box),
152 and the other 270 mg P spread throughout the background soil (13.5 kg soil), resulting
153 in 170 and 20 mg P kg^{-1} soil in the P-rich zone and the background soil, respectively
154 (heterogeneous treatment).

155 Based on the size of the rhizo-box and the soil volumes partitioned to neighbour,
156 P-rich patch and the zone beyond the patch (Fig. 1c), total soil (15 kg) was divided
157 into three lots: 10.5 kg soil in volumes 1 and 2, 1.5 kg soil in the P-rich patch (volume
158 3) and 3 kg in soil volume beyond the P-rich patch (volume 4). Before loading the soil
159 into the rhizo-box, the corresponding nutrients were added and thoroughly mixed with
160 the soil. With the help of several thin plastic separators of different sizes, we loaded
161 the soil into the corresponding rhizo-box zones.

162 The cultivar of maize (*Zea mays* L.) was ZD958, and the cultivar of faba bean
163 (*Vicia faba* L.) was Lincan5. Maize and faba bean seeds were surface-sterilized in
164 30% v/v H_2O_2 for 20 min, washed with deionized water, soaked in saturated CaSO_4
165 solution for 12 hours, and germinated on wet filter papers in Petri dishes for 4 days at
166 22 °C; seedlings were then transplanted into the rhizo-boxes. The target maize was
167 grown in the center of the rhizo-boxes; on one side, 8 cm away from the target maize
168 was a neighbouring plant (maize or faba bean), and 8 cm away from the target maize
169 on the other side was the P-rich zone (in the heterogeneous treatments) (Fig. 1c). This
170 design of the rhizo-box experiment allowed us to measure and monitor how the
171 neighbours affected target maize root foraging for the localized nutrient.

172 The experiment was conducted in a glasshouse at China Agricultural University,
173 Beijing (latitude: 40° 01' N, longitude: 116° 16' E). Temperature in the glasshouse
174 was maintained at 23-27 °C during the day and 13-16 °C at night, with a 13:11 h

175 light:dark cycle. The plants were gently watered every day to maintain field capacity
176 (30%, v/v, checked by TDR100), and were allowed to grow for 45 days.

177 **Measurements**

178 **Root imaging.** Images of roots were taken with a BTC 2 Minirhizotron camera
179 system at 15× magnification. Three transects were used along the tube (see Fig. 1a),
180 allowing the visualization of roots above (top transect) and on either side (90° to the
181 top transect) in a clockwise or anti-clockwise direction. Given that small plants had
182 few roots in the sight of the camera before the 17th day, we took the first images on
183 day 18 after sowing. Digital images of roots were taken in 43 frames (1.35 cm × 2
184 cm) along each transect at 2-3 d intervals to track root growth across the patch or in
185 the related soil volume. After 44 days of growth, we took a final series of digital
186 images. On day 45, all plants were harvested.

187 **Shoot and root analyses.** After 45 days of plant growth, the target maize and
188 neighbouring species were sampled separately and divided into shoots and roots. To
189 trace root foraging patterns of target maize, we regarded the rhizo-box edge close to
190 the neighbour (i.e. opposite direction of the P-rich zone) as the starting point (0 cm) to
191 divide roots into four volumes of soil in the heterogeneous or homogeneous
192 treatments (Fig. 1c); volume 1: between the rhizo-box edge on the left-hand side and
193 the stem of target maize (0-20 cm); volume 2: between the stem of target maize and
194 the P-rich zone (20-28 cm); volume 3: P-rich zone (28-32 cm); and volume 4:
195 between the distal P-rich zone edge and the other rhizo-box edge (32-40 cm).

196 Shoots were oven-dried at 105 °C for 30 min and then at 65 °C for 3 days for dry
197 mass determination. Phosphorus concentration in shoots was determined after
198 digestion with a mixture of 5 mL of concentrated sulfuric acid and 8 mL of 30 % v/v
199 H₂O₂. Shoot P was analyzed by the molybdovanadophosphate method
200 spectrophotometrically (UVmini-1240, Kyoto, Japan) at 440 nm (Johnson & Ulrich,
201 1959).

202 At harvest, the removable side of the rhizo-box was taken off, the soil was brushed
203 away little by little from roots, and the neighbouring maize was removed carefully,

204 whereas the target maize roots stayed undisturbed; then, the root system of target
205 maize was cut into four parts corresponding to soil volumes 1, 2, 3 and 4 (Fig. 1c). In
206 the maize/faba bean treatments, maize roots and faba bean roots could be
207 distinguished by color, i.e. maize roots were whitish and faba bean roots brownish;
208 after root removal, the soil was sectioned into four parts and roots were further
209 sampled.

210 Roots were placed in an icebox for transport to the lab and were then washed in
211 deionized water. The target maize roots were scanned on an EPSON root scanner at
212 400 dot-per-inch resolution (Epson Expression 1600 pro, Model EU-35, Tokyo,
213 Japan), and were then dried at 65 °C for 3 days for the root mass measurement. The
214 root length was analyzed by Win-RHIZO software (Regent Instruments Inc., Quebec,
215 QC, Canada). The length of fine roots (diameter ≤ 0.2 mm) was calculated based on
216 the classification of root diameters by Win-RHIZO software.

217 **Statistical analyses**

218 To assess the horizontal root distribution pattern of target maize, root mass production
219 towards either the neighbouring plants or the P-rich zone (i.e. root-placement pattern)
220 was analyzed by comparing root mass in region A (Fig. 1c) to the summed root mass
221 in region B (including soil volumes 2, 3 and 4) (Fig. 1c).

222 The proportion of root overlap between two neighbouring plants per unit area was
223 calculated from the minirhizotron camera images (1.35 cm \times 2 cm) to evaluate
224 difference in the root-placement patterns between the maize/maize and maize/faba
225 bean treatments (see Fig. 1c). Root length overlap was analyzed in the minirhizotron
226 camera images using WinRhizoTron V. 2005 software (Regents Inc., Quebec, QC,
227 Canada), and was divided by the total observable area in region A to assess how long
228 both types of roots grew together per unit soil area.

229 To estimate how roots proliferate in specific soil zones when responding to
230 neighbouring species, we measured the proportion of the target maize total root length
231 and the fine root (diameter ≤ 0.2 mm) length in the P-rich zone with respect to the total
232 root length in the whole rhizo-box in the heterogeneous treatment. Similarly, total root

233 length and fine root length in the soil volume corresponding to P-rich patch were
234 divided by total root length of the target maize in the whole rhizo-box; both root traits
235 were used to compare foraging capacity in the homogeneous with heterogeneous
236 treatments (Mou *et al.*, 1997; Jing *et al.*, 2010; Li *et al.*, 2014b; Wen *et al.*, 2017).

237 The days the target maize roots needed to reach, and grow out of, the P-rich zone
238 were also recorded to evaluate foraging pattern. When the roots of the target maize
239 were observed by the camera in soil volume 3 (the P-rich zone) in three transects, the
240 day was recorded as the time roots grew into the P-rich zone. The patch-leaving time
241 (when the roots grew out of the P-rich zone into volume 4) was recorded by the same
242 method.

243 We used the one-way analysis of variance (ANOVA) to test the effects of
244 neighbour species on shoot biomass, P uptake, root distribution patterns and root
245 foraging strategies of target maize. When appropriate, post-hoc mean comparisons
246 were conducted using the Tukey's test at 5% probability ($P \leq 0.05$) using the SPSS
247 statistical software (SPSS version 23.0, IBM SPSS Inc., Chicago, IL, USA). Student's
248 t-tests were conducted to detect significant differences in the variables between the
249 homogeneous and heterogeneous treatments.

250 **Results**

251 *Target maize shoot mass and P content*

252 The target maize shoot mass and P content were greater in maize/faba bean than
253 maize/maize in either the homogeneous or heterogeneous P-supply treatment, even
254 though maize shoot mass and P content were reduced in the mixture relative to single
255 maize (Figs. 2a, 2b). Heterogeneous P supply increased maize shoot mass (Fig. 2a)
256 and P content (Fig. 2b) in the maize/maize and maize/faba bean systems, whereas it
257 had no significant effect on the shoot biomass and P content of individually grown
258 maize (compared to the same dose of soil P that was distributed homogeneously).
259 Additionally, neighbouring faba bean combined with the heterogeneous P supply
260 stimulated maize growth, resulting in increased maize shoot biomass and P uptake in

261 maize/faba bean in the heterogeneous P treatment compared with maize in
262 maize/maize in the homogeneous P treatment (Fig. 2).

263 *Root distribution patterns of target maize*

264 The interaction between neighbour species and nutrient distributions influenced maize
265 total root mass (Figs. 3a, 3b; Table S1). In the homogeneous P supply treatment, total
266 root mass of target maize was lowest in maize/faba bean, followed by the
267 maize/maize and then individual maize treatments (Table S1). In the heterogeneous
268 treatment, total root mass of target maize was lowest in the maize/faba bean
269 treatment, and did not differ between the individual maize and the maize/maize
270 treatments. Compared with maize (single maize and target maize in maize/maize and
271 maize/faba bean) in the homogeneous treatments, heterogeneous P supply increased
272 total root mass of target maize in the maize/maize and maize/faba bean systems, and
273 for individual maize the trend was in the same direction, but not significant.

274 Comparing the root mass investment by target maize in the two soil volumes
275 (region A with neighbour and region B with P-rich zone or equivalent in the
276 homogeneous P environment, Fig. 1c), individually grown maize proliferated the
277 same amount of roots on the sides with and without the nutrient patch (Figs. 3a, 3b).
278 However, root proliferation varied in response to the combination of neighbour
279 species and nutrient patch location. In the homogeneous P treatment, maize grew
280 more roots on the side away from a neighbour, regardless of whether the neighbour
281 was maize or faba bean. In contrast, in the heterogeneous P treatment, maize grown
282 with faba bean produced similar root mass on the neighbour and the P-rich sides, but
283 increased root allocation on the neighbour-free/P-rich side when grown with
284 neighbouring maize.

285 Even though the maize grown with faba bean did not alter root distribution
286 between the two sides of the rhizo-boxes (with neighbour vs with P-rich patch; Fig.
287 3), the proportion of root overlap between target maize and neighbouring plants (Fig.
288 4) and their root images (Figs. 5, S1) taken by the camera both proved an adjustment
289 in maize root placement within the soil zone shared with the faba bean neighbour.

290 When soil P was homogeneously distributed (Figs. 4a, 4b), the proportion of root
291 overlap between maize and neighbouring faba bean in region A was greater than the
292 root overlap between maize and neighbouring maize in the maize/maize treatment at
293 day 44 (Fig. 4c), although it was similar after 30 and 37 days (Figs. 4a, 4b). In the
294 heterogeneous treatment, the proportion of root overlap per unit of soil area was
295 greater in the maize/faba bean treatment than maize/maize after 30, 37 and 44 days
296 (Fig. 4). The soil P supply pattern had little impact on this proportion of root overlap
297 between target maize and neighbouring plants, except for the maize/maize mixture at
298 day 37 (Fig. 4b). In addition, root images taken with the camera showed that when
299 maize and faba bean roots co-occurred, maize roots grew alongside the faba bean
300 roots regardless of the P supply pattern (Fig. 5; also see Fig. S1).

301 *Root foraging strategies for heterogeneously-supplied P*

302 Under homogeneous P supply, the presence of neighbours (either maize or faba bean)
303 increased maize root foraging capacity in the soil zone corresponding to the P-rich
304 patch location compared with the single maize treatment (Figs. 6a, 6b). When soil P
305 was heterogeneously distributed, neighbouring faba bean did not affect the proportion
306 of target maize total root length and the fine root (diameter ≤ 0.2 mm) length in the
307 P-rich zone (Figs. 6a, 6b). In contrast, neighbouring maize stimulated target maize
308 root proliferation (Fig. 6a), but not that of fine roots (Fig. 6b), in the P-rich location.
309 Hence, the target maize showed lower foraging capacity in the P-rich patch in the
310 maize/faba bean than maize/maize treatments (Figs. 6a, 6b). Compared with maize in
311 the homogeneous P treatment, the heterogeneous P had no effect on root foraging
312 capacity of target maize grown with faba bean, but improved maize root foraging
313 capacity in single maize and maize/maize (Figs. 6a, 6b).

314 The time roots of target maize required to reach and grow beyond P-rich zone (or
315 the corresponding soil volume in the homogeneous treatment) was recorded to
316 examine the capacity of roots to seek nutrients (Fig. 7). In the homogeneous and
317 heterogeneous treatments, neighbouring faba bean had no impact on time maize roots
318 spent reaching and growing out of the P-rich zone in maize/faba bean. However, the

319 time maize reached and exited the P-rich zone was shorter in the maize/maize than
320 single maize treatments. The time in which target maize roots entered and exited the
321 P-rich zone was longer in maize/faba bean than maize/maize except for the time
322 maize took to reach P-rich patch in the homogeneous treatment. The difference in
323 time the target maize exited the P-rich patch in maize/faba bean and maize/maize was
324 confirmed by the greater target maize root mass and total root length in the soil zone
325 beyond the P-rich patch in the maize/maize than maize/faba bean treatments (Fig. S2).
326 The P supply treatments did not influence the time roots took to reach or grow beyond
327 the P-rich zone (or corresponding soil volume in the homogeneous treatment)
328 regardless of neighbours (Fig. 7).

329 **Discussion**

330 Our results clearly indicated that plant neighbour presence altered the maize root
331 system spatial symmetry. Root growth of an individual plant is generally symmetrical
332 around the plant axis under homogeneous soil nutrient supply (Brisson & Reynolds,
333 1997; Schenk, 2006). In the present study, single maize grown in the homogeneous-P
334 treatments produced similar root mass in the two soil volumes adjoining its axis,
335 suggesting a balanced investment in development of individual maize roots (Fig. 3).
336 However, any neighbours to maize represented potential competition, but
337 neighbouring faba bean was less competitive than neighbouring maize (Zhang *et al.*,
338 2016). Plants appear to minimize neighbour competition by directing assimilates to
339 roots in soil away from the neighbouring plant, thereby enhancing root development
340 in those zones and reducing competitive encounters (Figs. 3, 4) (Maina *et al.*, 2002;
341 Callaway *et al.*, 2003; Jesch *et al.*, 2018). Although the present study did not consider
342 root locations in vertical direction because species tested used different depths in soil
343 profile as part of their foraging strategy (Li *et al.*, 2006), the results clearly indicated
344 that once neighbouring maize or faba bean was present, greater root mass was
345 distributed in the soil region away from the neighbouring plant in a horizontal
346 direction, more so in maize/maize than maize/faba bean.

347 In maize/maize, the target maize preferentially allocated the root mass into the soil
348 volume away from the neighbouring maize (Fig. 3), leading to the formation of
349 individual plant root territories as mentioned elsewhere (Caldwell *et al.*, 1991; Schenk
350 *et al.*, 1999), so that the new roots could increase nutrient acquisition by avoiding
351 competition for the same nutrient resources. Compared with maize grown with maize,
352 the spatial distribution of maize roots in maize/faba bean was determined by several
353 factors as follows. Firstly, in contrast to maize, faba bean could access the insoluble
354 soil organic/inorganic P fractions (unavailable to maize) by exuding carboxylates and
355 acid phosphatase, suggesting faba bean and maize had different soil P niches, as
356 mentioned in the published reports (Li *et al.*, 2007, 2014a; Hinsinger *et al.*, 2011).
357 Secondly, the proportion of root overlap was greater in maize/faba bean than
358 maize/maize, indicating a tendency of maize roots to grow along faba bean roots
359 (Figs. 4, 5, S1). Hence, the increased P availability induced by faba bean root
360 exudates could support not just faba bean growth, but also that of maize. Thirdly, in
361 addition to P mobilization by faba bean in the rhizosphere, the smaller and more
362 shallow root system of faba bean compared with neighbouring maize could allow a
363 greater soil volume (see also Li *et al.*, 2006; Zhang *et al.*, 2016) to be explored by
364 roots of the target maize in the maize/faba bean than in the maize/maize mixtures; this
365 idea was also supported by a previous study on maize/bean and maize/bean/squash
366 system (Postma & Lynch, 2012). Hence, belowground competition for nutrients
367 between target maize and neighbouring plants in maize/maize or maize/faba bean is
368 fundamental for determining maize root system distribution through the soil.
369 However, how root size and root exudation separately shape the response pattern of
370 targeted maize roots warrant further investigation. In summary, the results indicated a
371 role of the root/rhizosphere interactions driven by the neighbouring species in
372 regulating the spatial asymmetry of maize roots in the maize/faba bean compared with
373 maize/maize mixture.

374 The neighbour-induced rooting patterns (Figs. 3, 4, 5, S1) and their roles in
375 modifying target plant root foraging for nutrients, particularly in the nutrient-rich
376 zones (Figs. 6, 7), were characterized in the present study. Before roots touched the

377 P-rich patch, maize root foraging behaviours were mainly influenced by neighbours.
378 Compared with neighbouring maize, target maize roots tended to stay close to the
379 neighbouring faba bean (region A) because faba bean mobilized soil P by exudation
380 to feed maize in the soil (i.e. in soil with increased Olsen-P concentration) (Figs. 4, 5,
381 S1) rather than extend only into the P-rich patch. Hence, the time required to reach the
382 P-rich zone by target maize was longer in maize/faba bean than maize/maize (Fig.
383 7a). After reaching the patch, root proliferation in P-rich patch was affected by both
384 neighbouring species and heterogeneously-supplied P. Due to the lower root biomass
385 allocated to P-rich patch by target maize in maize/faba bean than maize/maize (Fig.
386 3), maize produced shorter total root length and fine roots length in P-rich patch (Fig.
387 6), inducing a lower nutrient depletion rate in P-rich soil volume (Padilla *et al.*, 2013;
388 Zhang *et al.*, 2019) but had longer time for nutrient acquisition and growing out of the
389 patch in maize/faba bean than maize/maize (Figs. 7b, S2). Consistent with the
390 previous study showing that the capacity of plants to proliferate roots into
391 nutrient-rich patches was linked with the distribution of the root system through the
392 soil (McNickle *et al.*, 2015), the results presented here showed a substantial role of
393 the neighbouring faba bean with low root morphological changes but high
394 physiological activity in regulating the target maize root placement pattern, and thus
395 root foraging strategies in the P-rich patches (hypothesis 1).

396 One of the most interesting arguments is the optimality of plant performance
397 governed by the foraging strategies (Weiner *et al.*, 2010; Anten & Vermeulen, 2016).
398 Optimal foraging does not mean that an organism must always respond to a resource
399 stimulus (Clergue *et al.*, 2005; Gordon, 2011) as has been assumed and expected in
400 many plant studies. Indeed, the reduced proliferation of target maize roots in the
401 P-rich zones when grown with faba bean possibly minimized the carbon cost and
402 increased efficiency of P capture as reported before (McNickle & Cahill, 2009;
403 Lynch, 2015). This study provides a direct support to the idea that an adaptive
404 response should increase the benefits, while minimizing the costs, of a set of
405 responses, subject to certain constraints (Smith, 1978). In the present study maize
406 roots grew along faba bean roots and could capture the P mobilized by faba bean in

407 the common rhizosphere, thereby suppressing the need to forage for P in the P-rich
408 patch by proliferating roots, which would be associated with a relatively large carbon
409 cost.

410 In addition, maize in the maize/faba bean mixture could use the P in the soil
411 volume unoccupied by faba bean and also the P in the P-rich patch, leading to greater
412 maize P uptake and productivity in the maize/faba bean than maize/maize mixtures in
413 the rhizo-box (Fig. 2), which was confirmed by an additional field experiment (see the
414 methods and data in SI; Fig. S4). The present study integrated the multiple
415 environmental cues (neighbour and nutrient) for understanding of
416 biologically-complex interactions between rhizosphere properties and root foraging,
417 indicating that interspecific variation in behavioural types governed nutrient uptake
418 and crop yield (hypothesis 2).

419 Root foraging traits are the important drivers of many ecosystem processes, such as
420 carbon and nutrient cycling, and the formation and structural stability of soil (Bardgett
421 *et al.*, 2014). It is crucial to understand how different combinations of plant traits
422 (such as different phylogeny, root sizes and various resource-use strategies) affect
423 species coexistence and regulate ecosystem function. Understanding the details of
424 plant foraging behaviour can enhance our knowledge on root-root interactions and
425 nutrient-use efficiency as well as crop productivity, and contribute to revealing how
426 these processes vary in the changing environments (e.g. variable nutrient
427 concentrations and distribution patterns) in natural ecosystems, and how different trait
428 combinations can influence system functions and sustainability in agroecosystems.
429 For example, increasing biodiversity in agriculture (e.g. intercropping) could enhance
430 soil fertility without external inputs and protect crops against pests and diseases while
431 ensuring adequate crop productivity (see e.g. Brooker *et al.*, 2015; Gaba *et al.*, 2014;
432 Duchene *et al.*, 2017; Isbell *et al.*, 2017; Weiner, 2017). However, the success of this
433 agroecological practice depends to a great extent on local field conditions and is still
434 potentially diminished by competition between intercropped species, particularly
435 when influenced by unfavourable local climate, growth conditions, fertilization
436 practices or choice of species (Hauggaard-Nielsen & Jensen, 2005). The present

437 research underlines the importance of designing cropping systems based on ecological
438 principles and the delivery of ecosystem services (including crop yield) to enhance
439 agroecosystem sustainability and nutrient-use efficiency, and minimize substrate and
440 energy inputs, which is partially highlighted in the previous studies (Isbell *et al.*,
441 2017; Weiner, 2017). Hence, managing root foraging behaviours might allow
442 designing more productive and sustainable cropping systems and developing more
443 precise and efficient agronomic recommendations.

444 **Conclusions**

445 The results demonstrated that plant root foraging patterns emerge from the
446 interactions of soil nutrient distribution and neighbours presence. The
447 root/rhizosphere interactions induced by neighbours are the underlying mechanism
448 driving maize root spatial distribution and thus governing root foraging for
449 heterogeneously-supplied P. The target maize showed greater foraging capacity for P
450 in the P-rich soil zone in maize/maize cropping than maize/faba bean intercropping,
451 shown as greater total root length as well as fine root length in the P-rich patch, but
452 shorter time to reach, and grow out of, the P-patch zone. The effect of nutrient supply
453 and neighbours on changing root growth and positioning corresponded to increases in
454 the target maize P uptake and shoot mass (higher with the faba bean than maize
455 neighbour, and higher in heterogeneous than homogeneous P supply). Faba bean
456 intercropped with maize stimulated the target maize to acquire more P than
457 neighbouring maize did in maize/maize, which was consistent with the greater shoot
458 biomass of the target maize; the heterogeneous P supply further improved the target
459 maize P nutrition. The present study showed that intercropping maize with faba bean
460 and localized application of P increased the target maize P uptake and shoot biomass.

 639 for separate root harvesting, and the two regions (A and B) for the root-placement pattern
 640 analysis.

641 Fig. 2 Shoot mass (a) and shoot P content (b) of target maize in various planting
 642 patterns and with soil P supply as homogeneous (Hom) or heterogeneous (Het).
 643 Different lowercase letters denote significant differences ($P \leq 0.05$) among the target
 644 maize data in the single maize, maize/maize and maize/faba bean systems in the
 645 homogeneous treatments, and different capitals denote significant differences (P
 646 ≤ 0.05) in the heterogeneous treatments. Means + SE (n=6). For target maize, the
 647 t-tests were run to assess the differences in shoot mass or shoot P content between the
 648 heterogeneous and homogeneous treatments: *, $P \leq 0.05$; ns = not significant.

649 Fig. 3 Root mass of target maize (position 0 on the X-axis) in region A with a
 650 neighbour (a) and region B with the P-rich zone (vertical light brown column) (b) in
 651 various planting patterns and with homogeneous (Hom) or heterogeneous (Het) soil P
 652 supply. Different lowercase letters denote significant differences ($P \leq 0.05$) among the
 653 target maize data in the single maize, maize/maize and maize/faba bean systems in the
 654 homogeneous treatment, and different capital letters denote significant differences (P
 655 ≤ 0.05) in the heterogeneous treatment. The asterisks on the side of horizontal bars
 656 denote the differences in root mass between the homogeneous and heterogeneous
 657 treatments. The asterisks within horizontal bars represent the treatment differences in

658 root mass between region A containing a neighbour and region B containing the
 659 P-rich zone. The darkening bars from top to bottom represent planting patterns from
 660 single maize, maize/maize to maize/faba bean. Means + SE (n=6). The t-tests were
 661 run to detect significant difference between the heterogeneous and homogeneous
 662 treatments: *, $P \leq 0.05$; **, $P < 0.01$; ***, $P < 0.001$; ns = not significant.

663 Fig. 4 Proportion of root overlap between neighbouring two plants in region A (see
 664 Fig. 1c) calculated from the minirhizotron camera images that were taken at 10-cm
 665 depth after 30 (a), 37 (b) and 44 days (c) with soil P supply either homogeneous
 666 (Hom) or heterogeneous (Het). All images were taken in the soil volume bordered by
 667 the lines projected from the faba bean and maize stems in region A at 15×
 668 magnification. Different lowercase letters denote significant differences ($P \leq 0.05$)
 669 between the target maize data in the maize/maize and maize/faba bean systems in the
 670 homogeneous treatments, and different capital letters denote significant differences in
 671 the heterogeneous treatments ($P \leq 0.05$). Means + SE (n=6). The t-tests were run to
 672 detect significant difference between the heterogeneous and homogeneous treatments:
 673 * $P \leq 0.05$ and ns = not significant.

674 Fig. 5 Minirhizotron camera images at 10-13 cm depth taken after 23 days of growth
 675 (top row, 1-a and 2-a) and after 6 additional days (29 days of growth; bottom row, 1-b
 676 and 2-b), whereby roots of the target maize approached and grew along the faba bean
 677 roots. All images were taken in the soil volume bordered by the lines projected from
 678 the faba bean and maize stems in region A (see Fig. 1c) at 15× magnification. The
 679 numbers in the bottom right corner represent replications and the day when the image
 680 was taken. Note the maize roots (whitish roots indicated by blue arrows) growing
 681 along faba bean roots (brownish roots indicated by red arrows).

682 Fig. 6 Proportion of root length (a) and fine root (diameter ≤ 0.2 mm) length (b) of
 683 target maize in the P-rich zone with respect to the total (whole rhizo-box) root length
 684 as influenced by the P supply pattern (Hom, homogenous; Het, heterogeneous).
 685 Different lowercase letters denote significant differences ($P \leq 0.05$) among the target

686 maize data in the single maize, maize/maize and maize/faba bean systems in the
687 homogeneous treatments, and different capital letters denote significant differences (P
688 ≤ 0.05) in the heterogeneous treatments. Means + SE ($n=6$). The t-tests were run to
689 assess the differences in the target maize data between the heterogeneous and
690 homogeneous treatments: *, $P \leq 0.05$; **, $P < 0.01$; ns = not significant.

691 Fig. 7 The number of days the target maize roots needed to reach (a) and grow out of
692 (b) the P-rich zone in the single maize, maize/maize and maize/faba bean treatments
693 with soil P supply either homogeneous (Hom) or heterogeneous (Het). When the roots
694 of the target maize were observed by the camera in soil volume 3 (the P-rich zone)
695 (see Fig. 1c) from the three transects, that day was recorded as the time roots grew
696 into the P-rich zone. The patch-leaving time (when the roots grew out of the P-rich
697 zone into volume 4, Fig. 1c) was recorded by the same method. Different lowercase
698 letters denote significant differences ($P \leq 0.05$) among the target maize data in the
699 single maize, maize/maize and maize/faba bean systems in the homogeneous
700 treatments, and different capital letters denote significant differences ($P \leq 0.05$) in the
701 heterogeneous treatments. Means + SE ($n=6$). The t-tests were run to assess the
702 differences in the patch-reaching (a) and -leaving time (b) by target maize between
703 the heterogeneous and homogeneous treatments: ns = not significant.

Fig. 1 (a) Schematic diagram of the experimental rhizo-boxes with a horizontal tube for a minirhizotron camera. One side (40 cm long and 30 cm deep) of the rhizo-box was removable for ease of soil and root sampling. (b) Representation of experimental design with three planting treatments (left-to-right: single maize, maize/maize and maize/faba bean) in the homogeneous (Hom) and heterogeneous (Het) nutrient environments. (c) Arrangement of target maize (in the middle of the rhizo-box), neighbour (on the left side, represented by a red arrow) and P-rich zone (on the right side, vertical light brown column), the four soil volumes [→(1)←(2)←(3)←(4)←] for separate root harvesting, and the two regions (A and B) for the root-placement pattern analysis.

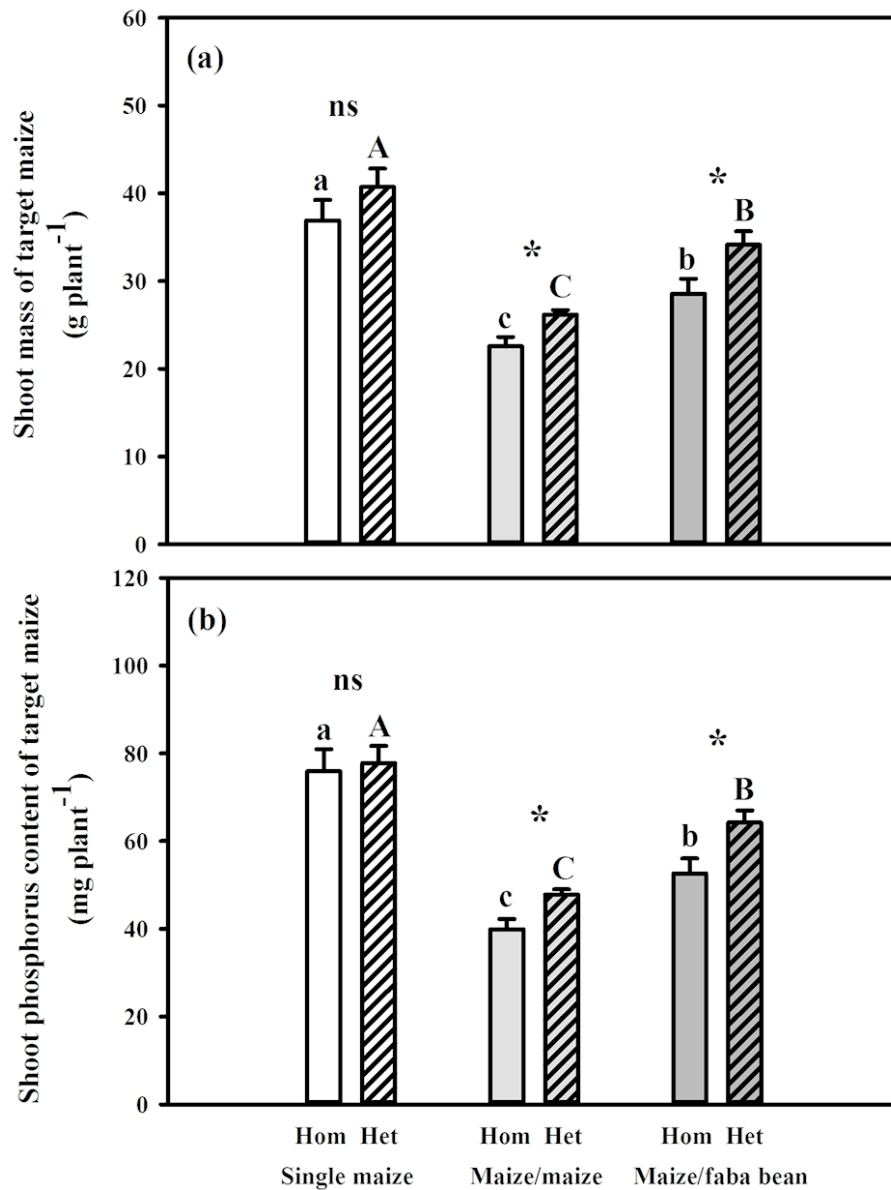

Fig. 2 Shoot mass (a) and shoot P content (b) of target maize in various planting patterns and with soil P supply as homogeneous (Hom) or heterogeneous (Het). Different lowercase letters denote significant differences ($P \leq 0.05$) among the target maize data in the single maize, maize/maize and maize/faba bean systems in the homogeneous treatments, and different capitals denote significant differences ($P \leq 0.05$) in the heterogeneous treatments. Means + SE ($n=6$). For target maize, the t-tests were run to assess the differences in shoot mass or shoot P content between the heterogeneous and homogeneous treatments: *, $P \leq 0.05$; ns = not significant.

Fig. 3 Root mass of target maize (position 0 on the X-axis) in region A with a neighbour (a) and region B with the P-rich zone (vertical light brown column) (b) in various planting patterns and with homogeneous (Hom) or heterogeneous (Het) soil P supply. Different lowercase letters denote significant differences ($P \leq 0.05$) among the target maize data in the single maize, maize/maize and maize/faba bean systems in the homogeneous treatment, and different capital letters denote significant differences ($P \leq 0.05$) in the heterogeneous treatment. The asterisks on the side of horizontal bars denote the differences in root mass between the homogeneous and heterogeneous treatments. The asterisks within horizontal bars represent the treatment differences in root mass between region A containing a neighbour and region B containing the P-rich zone. The darkening bars from top to bottom represent planting patterns from single maize, maize/maize to maize/faba bean. Means + SE ($n=6$). The t-tests were run to detect significant difference between the heterogeneous and homogeneous treatments: *, $P \leq 0.05$; **, $P < 0.01$; ***, $P < 0.001$; ns = not significant.

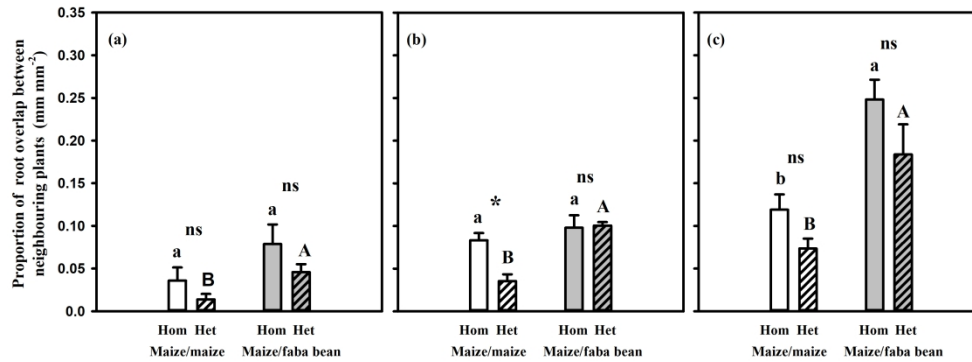

Fig. 4 Proportion of root overlap between neighbouring two plants in region A (see Fig. 1c) calculated from the minirhizotron camera images that were taken at 10-cm depth after 30 (a), 37 (b) and 44 days (c) with soil P supply either homogeneous (Hom) or heterogeneous (Het). All images were taken in the soil volume bordered by the lines projected from the faba bean and maize stems in region A at 15 \times magnification. Different lowercase letters denote significant differences ($P \leq 0.05$) between the target maize data in the maize/maize and maize/faba bean systems in the homogeneous treatments, and different capital letters denote significant differences in the heterogeneous treatments ($P \leq 0.05$). Means + SE ($n=6$). The t-tests were run to detect significant difference between the heterogeneous and homogeneous treatments: * $P \leq 0.05$ and ns = not significant.

301x109mm (300 x 300 DPI)

Fig. 5 Minirhizotron camera images at 10-13 cm depth taken after 23 days of growth (top row, 1-a and 2-a) and after 6 additional days (29 days of growth; bottom row, 1-b and 2-b), whereby roots of the target maize approached and grew along the faba bean roots. All images were taken in the soil volume bordered by the lines projected from the faba bean and maize stems in region A (see Fig. 1c) at 15 \times magnification. The numbers in the bottom right corner represent replications and the day when the image was taken. Note the maize roots (whitish roots indicated by blue arrows) growing along faba bean roots (brownish roots indicated by red arrows).

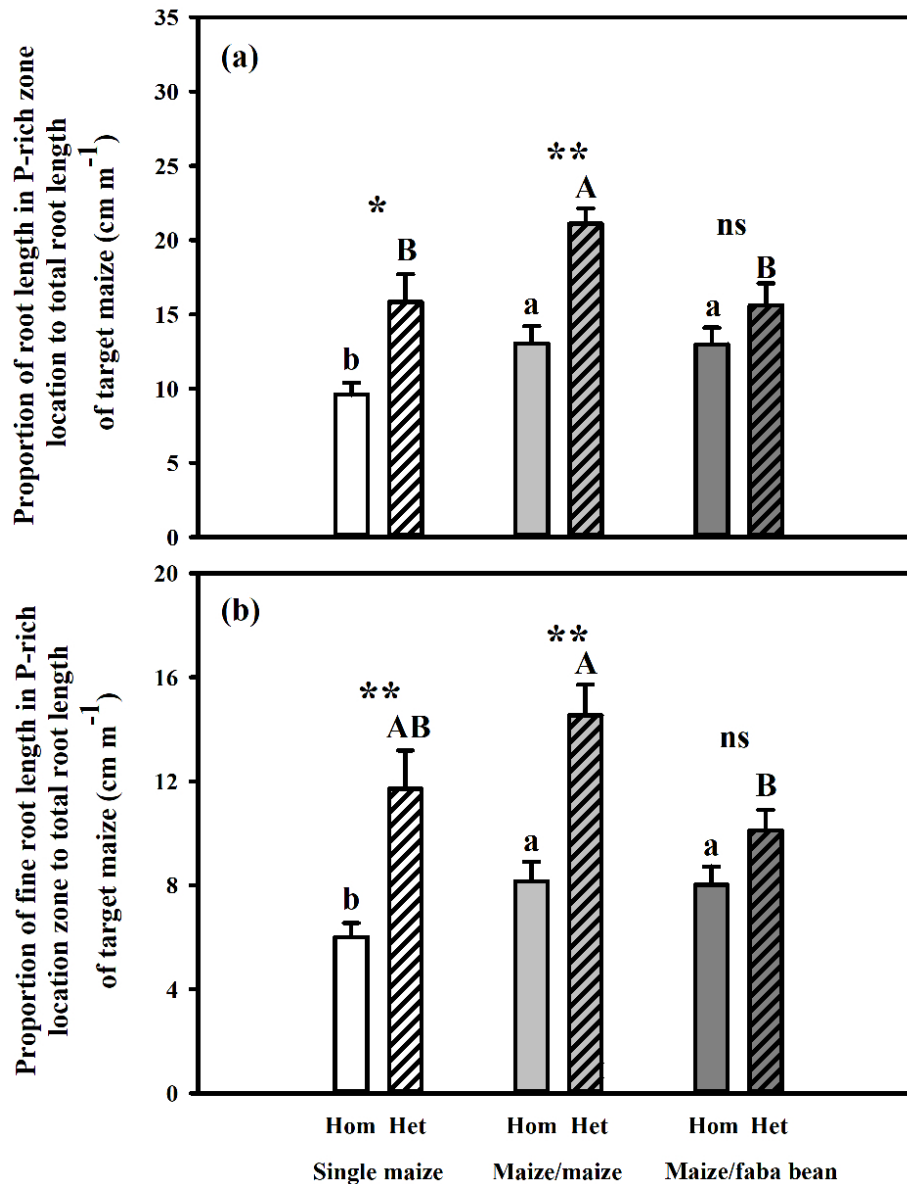

Fig. 6 Proportion of root length (a) and fine root (diameter ≤ 0.2 mm) length (b) of target maize in the P-rich zone with respect to the total (whole rhizo-box) root length as influenced by the P supply pattern (Hom, homogenous; Het, heterogeneous). Different lowercase letters denote significant differences ($P \leq 0.05$) among the target maize data in the single maize, maize/maize and maize/faba bean systems in the homogeneous treatments, and different capital letters denote significant differences ($P \leq 0.05$) in the heterogeneous treatments. Means + SE ($n=6$). The t-tests were run to assess the differences in the target maize data between the heterogeneous and homogeneous treatments: *, $P \leq 0.05$; **, $P < 0.01$; ns = not significant.

80x103mm (300 x 300 DPI)

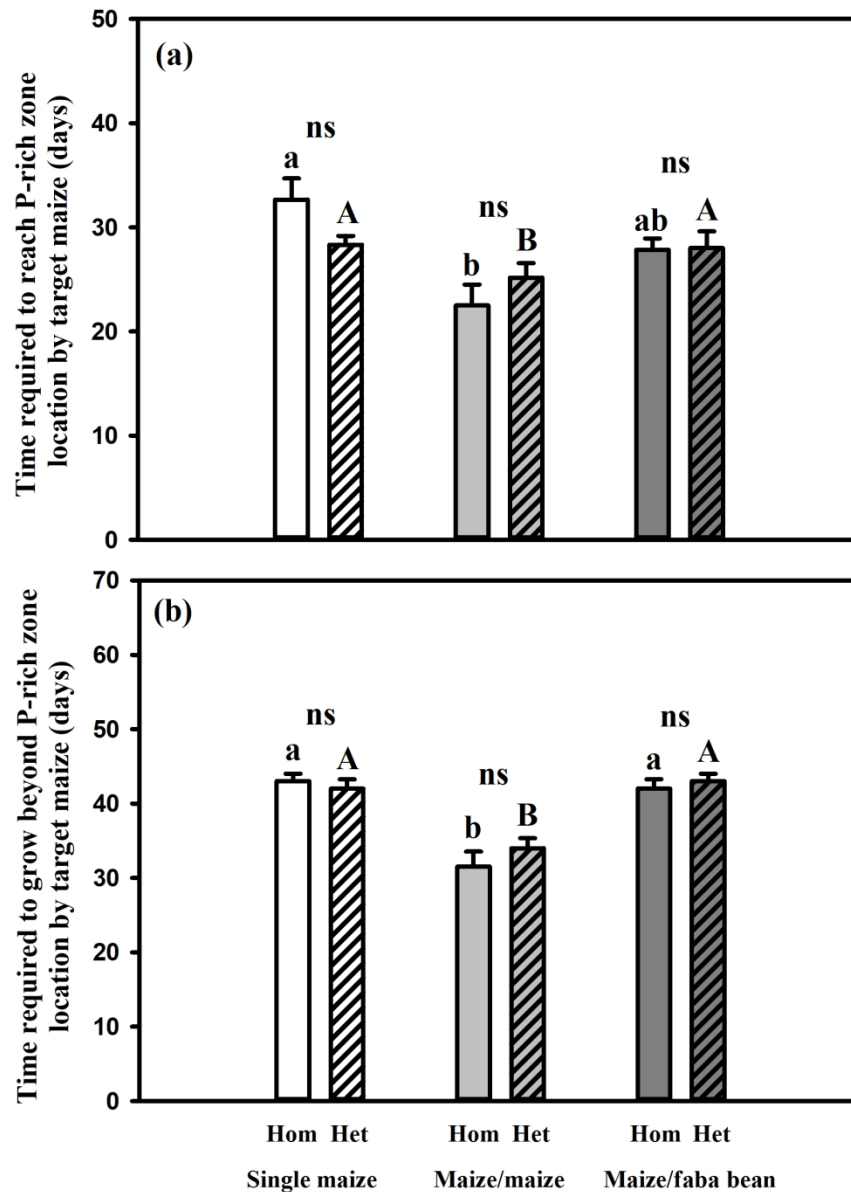

Fig. 7 The number of days the target maize roots needed to reach (a) and grow out of (b) the P-rich zone in the single maize, maize/maize and maize/faba bean treatments with soil P supply either homogeneous (Hom) or heterogeneous (Het). When the roots of the target maize were observed by the camera in soil volume 3 (the P-rich zone) (see Fig. 1c) from the three transects, that day was recorded as the time roots grew into the P-rich zone. The patch-leaving time (when the roots grew out of the P-rich zone into volume 4, Fig. 1c) was recorded by the same method. Different lowercase letters denote significant differences ($P \leq 0.05$) among the target maize data in the single maize, maize/maize and maize/faba bean systems in the homogeneous treatments, and different capital letters denote significant differences ($P \leq 0.05$) in the heterogeneous treatments. Means + SE ($n=6$). The t-tests were run to assess the differences in the patch-reaching (a) and -leaving time (b) by target maize between the heterogeneous and homogeneous treatments: ns = not significant.
