**Abstract**

Flow recession analysis, relating discharge  $Q$  and its time rate of change  $-dQ/dt$ , has been widely used to understand catchment scale flow dynamics. However, data points in the recession plot, the plot of  $-dQ/dt$  versus  $Q$ , typically form a wide point cloud due to noise and hysteresis in the storage-discharge relationship, and it is still unclear what information we can extract from the plot and how to understand the information. There seem to be two contrasting approaches to interpret the plot. One emphasizes the importance of the ensemble characteristics of many recessions (i.e., the lower envelope or a measure of central tendency), and the other highlights the importance of the event scale analysis and questions the meaning of the ensemble characteristics. We examine if those approaches can be reconciled. We utilize a machine learning tool to capture the point cloud using the past trajectory of daily discharge. Our model results for a catchment show that most of the data points can be captured using 5 days of past discharge. We show that we can learn the catchment scale flow recession dynamics from what the machine learned. We analyze patterns learned by the machine and explain and hypothesize why the machine learned those characteristics. The hysteresis in the plot mainly occurs during the early time dynamics, and the flow recession dynamics eventually converge to an attractor in the plot, which represents the master recession curve. We also illustrate that a hysteretic storage-discharge relationship can be estimated based on the attractor.

**1 Introduction**

Flow recession analysis (e.g., Barnes, 1939; Hall, 1968; Anderson & Burt, 1980; Brutsaert & Nieber, 1977) has been extensively utilized to understand flow dynamics at the catchment scale (e.g., Vogel & Kroll, 1992; Clark et al., 2009; Jachens et al., 2020). Flow recession is a “data-based” catchment scale signature that encapsulates information about catchment characteristics and dynamics (e.g., Troch et al., 2013). The flow recession analysis also provides ways to estimate a type of the storage-discharge relationship (e.g., Kirchner, 2009; Dralle et al., 2018). Typically, the recession plot is constructed by plotting the rate of change in discharge  $-dQ/dt$  versus discharge  $Q$  in log-log scale, and patterns in the plot have been analyzed and linked to catchment scale processes and properties (e.g., Brutsaert & Nieber, 1977; Troch et al., 2013).

46 Brutsaert and Nieber (1977) showed that some patterns of data points in the flow  
47 recession plot can be explained by a hydraulic groundwater model, viz. the Boussinesq  
48 model. The explanatory power of the model implies that catchment scale properties, such  
49 as the saturated hydraulic conductivity and the drainable porosity, can be estimated through  
50 the flow recession analysis (Brutsaert & Nieber, 1977; Troch et al., 2013). Other stud-  
51 ies showed that the data points can also be explained by other mechanisms and mod-  
52 els, such as a two parallel bucket model and a model using superposition of multiple lin-  
53 ear reservoirs (e.g., Clark et al., 2009; Harman et al., 2009; Gao et al., 2017). Biswal and  
54 Marani (2010) showed that the geometry of drainage network also can explain some pat-  
55 terns. While which model represents reality better probably varies from site to site, it  
56 is clear that the recession analysis helps hydrologists develop hypotheses about catch-  
57 ment scale flow dynamics.

58 However, there still remains a fundamental issue on what is the “right” informa-  
59 tion we can extract from the signature. The data points in the recession plot usually form  
60 a wide point cloud due to the measurement noise in  $Q$  (e.g., Rupp & Selker, 2006), the  
61 auto-correlation in observation errors, and time-varying catchment dynamics and exter-  
62 nal forcings (e.g., Harman et al., 2009; Shaw & Riha, 2012; Jachens et al., 2020). Be-  
63 fore proposing hypotheses about catchment scale dynamics, we need to decide how to  
64 interpret the wide point cloud.

65 Brutsaert and Nieber (1977) suggested using the lower envelope of a point cloud.  
66 They used the lower envelope to capture the ensemble characteristics of many recessions  
67 (Brutsaert, 2005) and suggested determining the slope of the lower envelope  $b$  among the  
68 values that can be explained by the Boussinesq model instead of estimating the slope  
69 directly using data. The Boussinesq model used in their original study predicts two slopes,  
70  $b = 1.5$  for the late time recession and  $b = 3.0$  for the early time recession, and the  
71 predicted lower envelope has a lower slope in the lower discharge range. Alternatively,  
72 Vogel and Kroll (1992) performed an ordinary regression analysis to fit a line to the data  
73 as a measure of the central tendency (centrality). Similarly, Kirchner (2009) suggested  
74 binning the data and performed a weighted linear regression to account for the uncer-  
75 tainty associated with each bin.

76 However, recent studies have questioned the use of the lower envelope and the mea-  
77 sure of central tendency and have emphasized the importance of analyzing the slope  $b$

78 of each recession event (e.g., Shaw & Riha, 2012; Tashie et al., 2020; Jachens et al., 2020).  
79 The slope fitted to the data points of each event is event-specific, and it seems that the  
80 lower envelope does not represent an ensemble characteristics of recession dynamics but  
81 is a collection of endpoints of each event (Tashie et al., 2020; Jachens et al., 2020). Such  
82 event-to-event differences are often attributed to catchment memory effects (e.g., Har-  
83 man et al., 2009; Tashie et al., 2020; Jachens et al., 2020) or to seasonal dynamics (Shaw  
84 & Riha, 2012). Spatial and temporal pattern of external forcings, such as evapotranspi-  
85 ration and precipitation, may also affect the event-to-event variability (Wang & Cai, 2010;  
86 Szilagyi et al., 2007). Besides, the slope of each event is in general much steeper than  
87 the slope estimated as a central tendency or derived from the Boussinesq model (e.g.,  
88 Tashie et al., 2020; Jachens et al., 2020). Tashie et al. (2020) further argued that many  
89 of the trajectories of each event in the recession plot have a higher slope at the lower dis-  
90 charge range, except for some dry and flat catchments, casting doubt on the applicabil-  
91 ity of the Boussinesq model.

92 There seem to be two contrasting approaches. One emphasizes the importance of  
93 analyzing the ensemble characteristics of many recessions (i.e., the lower envelope or a  
94 measure of central tendency), and the other highlights the importance of the event scale  
95 analysis and questions the meaning of the ensemble characteristics that are represented  
96 by the lower envelope or the measure of central tendency. In this study, we examine if  
97 those approaches can be reconciled. We utilize a machine learning tool to capture dy-  
98 namics represented in the recession plot using the past trajectory of daily flow. We an-  
99 ticipate that the tool can learn both the time-variability (i.e., the event-to-event vari-  
100 ability) and the ensemble characteristics of recession dynamics, if both exist. We report  
101 the machine learning model results and explain some patterns that the machine learn-  
102 ing tool exposed for a study catchment. We finally show that the contrasting approaches  
103 can be combined into a single one. While the focus of our study is not on examining un-  
104 derlying hydrological processes in detail, we also infer and hypothesize underlying hy-  
105 drological processes in the catchment. In addition, we illustrate that a hysteretic storage-  
106 discharge relationship can be estimated using a characteristic trajectory that appears  
107 in the recession plot. In the discussion section, we treat the recession plot as a phase space  
108 plot, and links to other phase space plots are also discussed.

## 2 Theoretical background, methods, and study site

### 2.1 Flow recession analysis

Originally, flow recession analysis used a plot of  $-dQ(t)/dt$  versus  $Q(t)$ . In this study, we use an alternative function:

$$g(t) = -\frac{dQ(t)}{dt}/Q(t) \quad (1)$$

The function  $g(t)$ , instead of  $-dQ/dt$ , is plotted versus  $Q(t)$ . The function  $g$  is identical to the catchment sensitivity function of Kirchner (2009). Note that the catchment sensitivity function expresses the sensitivity of discharge to changes in storage  $S$ ; i.e.,  $g = dQ/dS = (dQ/dt)/(dS/dt)$  (Kirchner, 2009). The formulation in (1) is a simplified form for the case of negligible precipitation and evapotranspiration during recession periods that has been utilized predominantly instead of fully considering  $dS/dt$ . We will use the term recession plot interchangeably for either the  $g$  vs.  $Q$  plot or the  $-dQ/dt$  vs.  $Q$  plot. When a power function is used to characterize the original recession plot (i.e.,  $-dQ/dt = aQ^b$ ), the power function still holds in the  $g$  vs.  $Q$  plot with the exponent decreased by 1:  $g(Q) = aQ^{b-1}$  (Kirchner, 2009).

The catchment sensitivity function can be used to characterize flow recession dynamics and estimate a type of storage-discharge relationship. The inverse of  $g$ ,  $1/g$ , is a time scale of the flow recession. When the flow recession over time is approximated using an exponential function as  $Q = Q_0 e^{-t/t_c}$ , where  $t_c$  is the e-folding time of the exponential decay,  $1/g$  is constant and is the e-folding time; i.e.  $t_c = 1/g$ . Otherwise, the decay rate  $1/g$  depends on time. Also, assuming there is a one-to-one and invertible function that relates  $g$  to  $Q$ , the function  $g(Q)$  can be utilized to estimate a relationship between the active storage and discharge using:  $S_a(Q) = \int_{Q_0}^Q (1/g(Q))dQ$ , where  $S_a$  is the “active” storage (relative to a certain storage at  $Q_0$ ) which is the portion of the storage that drives discharge (e.g., Kirchner, 2009; Troch et al., 2013). Note that the active storage is sometimes referred to as “dynamic” storage (Staudinger et al., 2017), “direct” storage (Dralle et al., 2018), or “hydraulically-connected” storage (Carrer et al., 2019).

Several methods have been suggested to estimate  $dQ(t)/dt$  using the discrete time series of  $Q$ . One simple way is to estimate it at a constant time step (CTS):  $dQ(t+\Delta t/2)/dt = (Q(t + \Delta t) - Q(t))/\Delta t$ , where  $\Delta t$  is the time step and  $Q(t + \Delta t/2) = (Q(t + \Delta t) +$

138  $Q(t))/2$  (Brutsaert & Nieber, 1977). However, the method is sensitive to discharge mea-  
 139 surement resolution and noise, especially at low flow (Rupp & Selker, 2006). Roques et  
 140 al. (2017) suggested the exponential time step (ETS) method, where the time step in-  
 141 creases exponentially in each recession event and an exponential function is fitted to dis-  
 142 charge, which is then used to estimate its (smoothed) time derivative.

143 Also, several criteria to determine recession periods have been suggested. Brutsaert  
 144 and Nieber (1977) originally proposed using data for periods of  $dQ/dt < 0$  and at least  
 145 5 days after any precipitation event, with the expectation that it would eliminate as much  
 146 as possible direct surface recession flow. Recent studies have refined the criteria. For ex-  
 147 ample, in the event-by-event analysis, a sufficient number of samples is required for each  
 148 event to fit a statistically meaningful (power) function. Dralle et al. (2017) suggested us-  
 149 ing events that have strictly decreasing  $Q$  for more than four days (when one uses daily  
 150 time step data). The start and end times of each event can be determined using a time  
 151 series of precipitation  $J$  (Lamb & Beven, 1997; Dralle et al., 2017) or based on the tran-  
 152 sition from decreasing discharge to increasing discharge and vice versa (Dralle et al., 2017;  
 153 Jachens et al., 2020). Those event-based studies either do not exclude any periods af-  
 154 ter peak flow (Dralle et al., 2017; Tashie et al., 2020) or exclude only one day after the  
 155 peak flow (Jachens et al., 2020). In addition, Lamb and Beven (1997) suggested filter-  
 156 ing out periods with significant (potential) evapotranspiration. For the catchment sen-  
 157 sitivity function, Kirchner (2009) proposed using the  $Q \gg J$  and  $Q \gg ET$  crite-  
 158 ria, where  $ET$  is the evapotranspiration rate, to rule out the effects of those climate forc-  
 159 ings.

160 As mentioned earlier, the function  $g(Q)$  (or  $-dQ/dt$ ) has been parameterized us-  
 161 ing single discharge values  $Q$ . However, according to some studies that explain the event-  
 162 to-event time-variability as memory effects (e.g., Harman et al., 2009; Jachens et al., 2020;  
 163 Tashie et al., 2020), it seems more natural to parameterize  $g$  using the past trajectory  
 164 of measurable variables. In this study, we use the past trajectory of discharge to better  
 165 characterize  $g$ , rather than using single discharge values.

166 By doing so, we capture a type of hysteresis in the flow dynamics that can be *ob-*  
 167 *served* during flow recession periods. One way to define hysteresis in hydrology is to de-  
 168 fine it as a phenomenon where the output of a system depends not only on the current  
 169 state of the system but also on the past trajectory of system states or inputs (Davies &

170 Beven, 2015). For catchment scale flow dynamics, discharge is the output, and storage  
 171 can be used to represent the state of a catchment. The hysteresis in the catchment scale  
 172 flow dynamics then manifests as a hysteretic storage-discharge relationship. The wide  
 173 point cloud in the recession plot illustrates the hysteresis between the “active” storage  
 174  $S_a$  and discharge  $Q$  during flow recession periods if the spread is not due to measure-  
 175 ment errors (see Figure 1). Theoretically, if there is no hysteresis between the active stor-  
 176 age and discharge, the data points in the recession plot should align on a single curve  
 177 (see Figure 1A). Earlier we introduced that parameterizing  $g$  using  $Q$ , i.e.,  $g(Q)$ , leads  
 178 to a non-hysteretic active storage-discharge relationship. Its inverse is also true; if the  
 179 active storage discharge relationship is non-hysteretic,  $g$  only depends on  $Q$  (see appendix  
 180 A1). Thus, capturing the point cloud is identical to capturing the hysteretic flow dynam-  
 181 ics during flow recession periods (see Figure 1B). Taking the well-known hysteresis in  
 182 the soil water retention curve as an example, what we do in this study as to which part  
 183 of the hysteresis we are looking at is similar to looking at only the drying part of the hys-  
 184 teresis in the soil water retention curve (i.e., the drying scanning curves). We should ex-  
 185 pect hysteresis in the catchment scale storage-discharge dynamics as a result of differ-  
 186 ences in the celerity and velocity responses to inputs. This also suggests that the hys-  
 187 teresis should be scale dependent (Beven & Davies, 2015; Beven, 2020b).

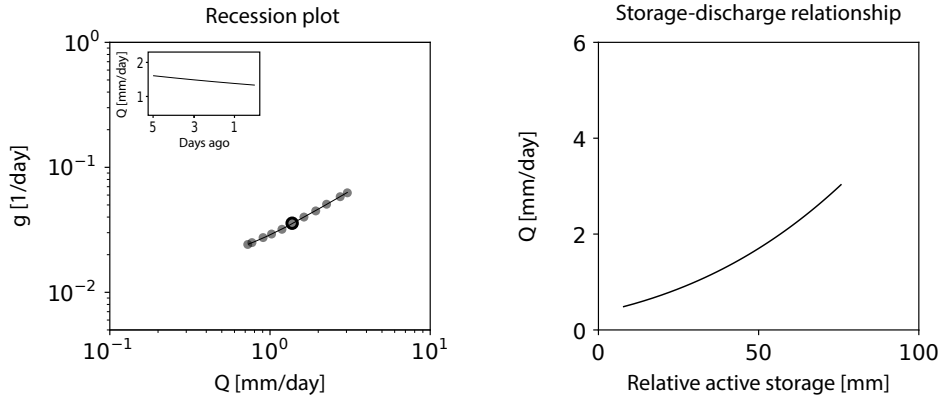

188 While the complete picture of the hysteresis cannot be examined, it is still mean-  
 189 ingful as the recession part of the hysteresis can be seen mainly based on discharge data,  
 190 which is arguably much less uncertain at the catchment scale than other fluxes (e.g.,  $J$   
 191 and  $ET$ ) (Kirchner, 2009). Other fluxes become much more important if we look at the  
 192 complete picture of the hysteresis. Nevertheless, in the later discussion, we will also briefly  
 193 show a possibility of estimating the (relative) total storage-discharge relationship using  
 194 a modified catchment sensitivity function, assuming the evapotranspiration rate is re-  
 195 liable.

196 The model to estimate  $g$  using the past trajectory of discharge can be written as:

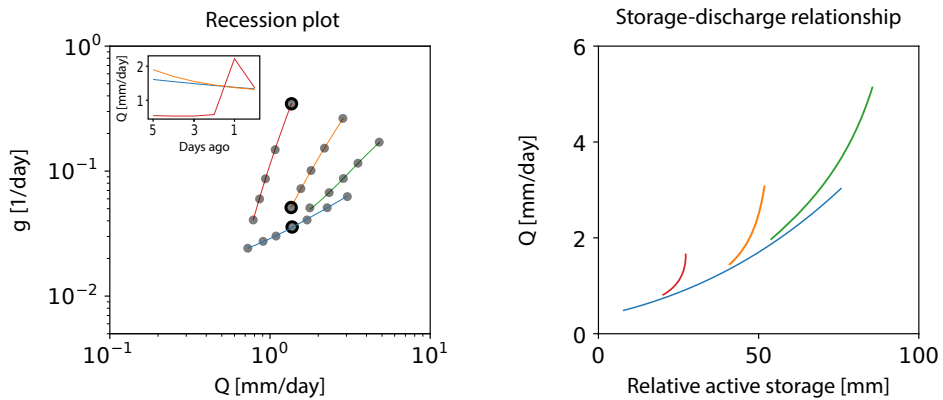

$$g = H(\overleftarrow{Q}) \quad (2)$$

197 where  $H$  is a non-linear hysteretic function, and  $\overleftarrow{Q}$  is the past trajectory of dis-  
 198 charge. Specifically, we configure the model to estimate the half-step ahead  $g$ ,  $g(t+\Delta t/2)$ ,  
 199 using  $Q(t)$ ,  $Q(t-\Delta t)$ ,  $\dots$ ,  $Q(t-m\Delta t)$ , where  $m+1$  is the length of the past trajec-

(A) No hysteresis

(B) Hysteresis exists

**Figure 1.** Illustration of the recession plot and the corresponding storage-discharge relationship (A) without hysteresis and (B) with hysteresis. The dots in the recession plot are a few selected data points. The lines in the recession plot show the trajectory of each event. The line color in (B) distinguishes events. When there is no hysteresis between the active storage and discharge, the data points in the recession plot align on a single curve. Otherwise, the hysteresis between the active storage and discharge leads to the scattered data points in the recession plot. The subset figures in both recession plots illustrate the past trajectories of discharge for events at the timings indicated by the black circles in the recession plot. The timing for each event was chosen when discharge is similar at about 1.5 mm/day. (The green event was excluded since discharge did not decrease to the value during the event.) We anticipate that the difference in  $g$  at similar discharge can be characterized by the past trajectory of discharge as shown in the subset figure. Note that the subset figure includes the rising limb of discharge for the red event because it includes the trajectory of discharge before the recession starts.

200 tory of discharge. Note that while  $g$  is estimated for the flow recession periods, the past  
 201 trajectory of discharge can include rising limbs. During the flow recession periods, the  
 202 model can estimate the one-step ahead discharge  $Q(t+\Delta t)$  using  $g(t+\Delta t/2)$  as:  $Q(t+$   
 203  $\Delta t) = \frac{2-g(t+\Delta t/2)\Delta t}{2+g(t+\Delta t/2)\Delta t}Q(t)$ , assuming that  $dQ/dt$  is constant between the two time steps.

204 The functional form is similar to Beven’s Holy Grail problem (Beven, 2006b), that  
 205 is to find a scale dependent hysteretic function for estimating discharge using the past  
 206 trajectory of precipitation  $J$  and other relevant inputs at the scale of interest. In this  
 207 study, we use the past trajectory of  $Q$  rather than  $J$ . One reason is that, often, discharge  
 208 data is more accurate than catchment scale estimation of  $J$ . Also, it is more consistent  
 209 with the previous studies where  $Q$  is used to characterize the function  $g$  (or  $-dQ/dt$ ).

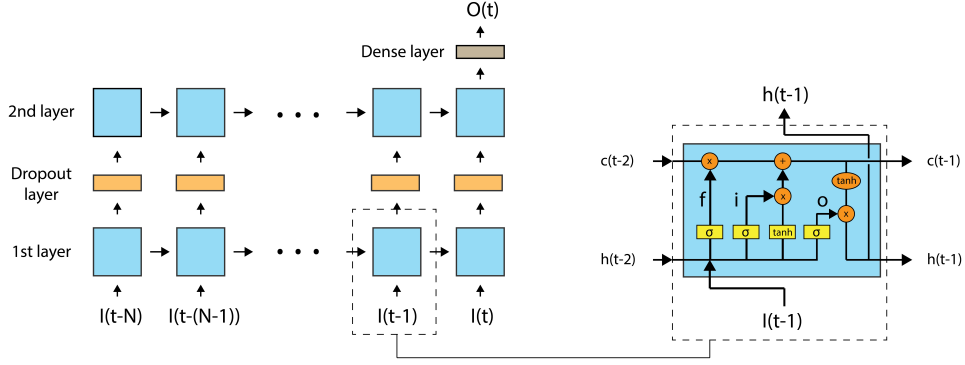

210 Following Young and Beven (1994), model (2) is a “data-based” model in the sense  
 211 that the model structure is not determined *a priori* as opposed to models in which those  
 212 structure is determined, for example, the multiple reservoir models (e.g., Clark et al.,  
 213 2009; Harman et al., 2009; Gao et al., 2017) or spatially-resolved continuum equation  
 214 based models such as the Richards equation based models. *A priori* determined model  
 215 structure may adversely affect interpretation of hydrologic dynamics based on model re-  
 216 sults due mostly to the uncertain model structures (e.g., Beven, 2006a; Kirchner, 2006;  
 217 Kim & Troch, 2020). The “data-based” modeling approach utilizes the transfer function  
 218 model (which is originally introduced in control theory;  $O(t) = (\sum_{i=0}^j b_i z^{-i} / (1 + \sum_{i=1}^k a_i z^{-i})) I(t)$ ,  
 219 where  $O$  is the output time series,  $I$  is the input time series,  $z$  is the backward opera-  
 220 tor,  $a_i$ ,  $b_i$ ,  $j$ ,  $k$  are the model parameters), as it has a general form that relates input and  
 221 output time series (e.g., Young, 2011). As we focus only on capturing the dynamics dur-  
 222 ing recession periods, the transfer function model may reduce to the auto-regressive (AR)  
 223 model where the output time series  $O(t)$  is modeled using its past history (i.e.,  $(1 + \sum_{i=1}^k a_i z^{-i})O(t) =$   
 224  $0$ ). Model (2) is similar to the auto-regressive model in that the model utilizes the past  
 225 history of output time series. While model (2) estimates  $g(t+\Delta t/2)$  not  $Q(t+\Delta t)$  as  
 226 our interest is on  $g$ , we showed above that  $Q(t+\Delta t)$  can be estimated using  $g(t+\Delta t/2)$ .  
 227 The wide point cloud in the recession plot implies that the parameters of the AR model  
 228 might need to vary over time to account for the non-linearity of the flow recession dy-  
 229 namics. Instead of estimating the time-variable parameters in classic ways, we utilize a  
 230 machine-learning tool to consider the non-linearity (see the next section for more details).

231 Also, model (2) can be thought of as a generalization of the model developed by  
 232 Fleming (2007). In his pioneering work Fleming (2007) developed a machine-learning based  
 233 model that predicts one step ahead discharge,  $Q(t + \Delta t)$ , using  $Q(t)$ , where the rela-  
 234 tionship between the two variables depends on  $Q(t)$ . Again, while model (2) estimates  
 235  $g(t+\Delta t/2)$  not  $Q(t+\Delta t)$ ,  $Q(t+\Delta t)$  can be estimated using  $g(t+\Delta t/2)$  by linear inter-  
 236 polation. The important difference between model (2) and that of Fleming is the use of  
 237 the past trajectory of  $Q$  in model (2) to capture the hysteretic flow recession dynamics.  
 238 Fleming’s model uses only  $Q(t)$  to estimate  $Q(t+\Delta t)$ , while our model utilizes a longer  
 239 past trajectory of  $Q$ .

## 240 **2.2 A machine learning tool: Long Short-Term Memory model**

241 Given the variability in  $g(t)$  we use a machine learning tool to learn the function  
 242  $H$  using data. Machine learning tools have been applied to model several hysteretic hy-  
 243 drologic dynamics that are represented in, for example, the rating curve (Tawfik et al.,  
 244 1997) and the soil water retention curve (Jain et al., 2004). We choose the LSTM model  
 245 as a machine learning tool. The LSTM model is a supervised learning algorithm and a  
 246 type of recurrent neural network, that has been applied successfully to reproduce catch-  
 247 ment scale flow dynamics (e.g., Kratzert et al., 2018; Shen et al., 2018). Compared to  
 248 the classic (or vanilla) recurrent neural networks, the LSTM model has several advan-  
 249 tages. The most well known advantage is the improved ability of the LSTM model in  
 250 remembering past information in memory (Greff et al., 2017).

251 A LSTM model can be configured with multiple layers such as the recurrent LSTM  
 252 layer, the dropout layer, and the dense layer (see Figure 2). The recurrent LSTM layer  
 253 consists of multiple LSTM cells, and a LSTM cell processes an internal state  $h$  and a cell  
 254 state (or a cell memory)  $c$  using input data  $I$  and three gates: a forget gate  $f$ , an input  
 255 gate  $i$ , and an output gate  $o$ . The states  $h$  and  $c$  are vectors of length  $n$ , where  $n \geq 1$   
 256 is referred to as the number of LSTM units. A set of forward operations in a LSTM cell  
 257 can be written as:

**Figure 2.** (Left) An example of a LSTM model structure with the dropout layer and the dense layer. The model has two layers of the recurrent LSTM layer with the dropout layer in between. Input time series  $I_t$  is fed into the first LSTM layer. The output of the second LSTM layer is fed into the dense layer, which estimates an output  $O_t$  of the model. (Right) A detailed structure inside a LSTM cell.  $h_t$  is the internal state and  $c_t$  is the cell state at time  $t$ .  $f$ ,  $i$ , and  $o$  denote the forget gate, the input gate, and the output gate, respectively.  $\tilde{c}$  is the cell input (modified from Greff et al. (2017)).

$$\begin{aligned}
 f_t &= \sigma(W_f I_t + U_f h_{t-1} + b_f) \\
 i_t &= \sigma(W_i I_t + U_i h_{t-1} + b_i) \\
 o_t &= \sigma(W_o I_t + U_o h_{t-1} + b_o) \\
 \tilde{c}_t &= \tanh(W_c I_t + U_c h_{t-1} + b_c) \\
 c_t &= f_t \circ c_{t-1} + i_t \circ \tilde{c}_t \\
 h_t &= o_t \circ \tanh(c_t)
 \end{aligned} \tag{3}$$

258 where  $f_t$ ,  $i_t$ ,  $o_t$ , and  $\tilde{c}_t$  are activation vectors (of length  $n$ ) of the forget gate, the  
 259 input gate, the output gate, and the cell input at time  $t$ , respectively,  $c_t$  is the cell state  
 260 vector of length  $n$ ,  $h_t$  is the internal state vector of length  $n$ ,  $\sigma$  is the sigmoid function,  
 261 the operator  $\circ$  denotes the Hadamard product (element-wise product),  $I_t$  is the input  
 262 feature vector of size  $m$  at time  $t$ , where  $m$  is the number of input features (or variables),  
 263  $W$  matrices ( $W_f$ ,  $W_i$ ,  $W_o$ , and  $W_c$ ) are  $n \times m$  weight matrices,  $U$  are  $n \times n$  weight ma-  
 264 trices, and  $b$  vectors are the bias vector of length  $n$ . The  $W$  and  $U$  matrices and the  $b$   
 265 vectors need to be learned using a dataset.

266 The dropout layer is to prevent the weights from co-adapting too much and reduce  
 267 overfitting (e.g., Hochreiter & Schmidhuber, 1997). The layer randomly sets a fraction  
 268 of variables (e.g., input sequence, output sequence, or the recurrent state of the previ-  
 269 ous time step) to zero at each iteration during training. The dropout rate, a hyperpa-  
 270 rameter associated with the layer, determines the fraction. The dense layer is a deeply  
 271 connected neural network layer, and it estimates:  $O_t = k(W_d \circ x_t + b_d)$ , where  $O_t$  is an  
 272 output sequence of length  $q$ ,  $x_t$  is a length  $q$  input sequence to the layer,  $W_d$  is a  $p \times$   
 273  $q$  weight matrix,  $b_d$  is a bias vector of length  $q$ , and  $k$  is an activation function such as  
 274 the linear function  $k(x) = x$ .

275 For example, the model shown in Figure 2 has two layers of the recurrent LSTM  
 276 layer with the dropout layer in between. The dense layer receives the output of the sec-  
 277 ond LSTM layer as an input sequence. The illustrated model uses  $N+1$  days (or time  
 278 steps) of input data (discharge  $Q$ ) to estimate an output  $g$ , i.e.,  $I_t = Q(t)$  and  $m = 1$   
 279 for the first layer, and  $O_t = g(t)$  with  $q = 1$ . Again, while  $g$  is estimated for recession  
 280 periods, the model input  $I_t$  can include discharge data in the rising limb. The number  
 281 of LSTM units for the first and the second layers are hyperparameters that need to be  
 282 determined by the modeler, and  $p$  is equal to the number of LSTM units of the second  
 283 LSTM layer.

284 The model needs to be trained using data to estimate the  $W$  and  $U$  weight ma-  
 285 trices and the bias vectors  $b$ . Usually, a neural network model is trained over the whole  
 286 data many times, where the number of iterations over the whole dataset is referred to  
 287 as the number of epochs. One epoch includes the whole dataset, and an epoch consists  
 288 of several batches that are a fraction of the dataset. For each batch, the forward pass  
 289 and the backward pass are performed to train the model using a loss function. The for-  
 290 ward pass is what Figure 2 and equation (3) describe; that is the update of the cell state  
 291 forward in time and according to the direction illustrated in the figure. The backward  
 292 pass, also called backpropagation, operates in the reverse manner compared to the for-  
 293 ward pass. It determines the gradient of the weights in those matrices and the vectors  
 294 to improve the model performance, and those weights are updated based on the gradi-  
 295 ent and a gradient descent optimization algorithm. The learning rate, a hyperparam-  
 296 eter, determines the step size of the update at each iteration.

297 Compared to the usual data based approach where the transfer function (or the  
298 auto-regressive model) is used, our approach using the ML model is different in the way  
299 that non-linearity is considered in the model. While several methods, such as estimat-  
300 ing time-variable or state-dependent parameters of the model, were developed to impose  
301 non-linearity in the transfer function model (or the AR model), those methods have their  
302 own disadvantages. For example, the time-variable parameter estimation method can-  
303 not track the true time-variability of the parameters if that time-variability is rapid (Young,  
304 2011). In our model, the non-linearity of the model is determined by the LSTM model  
305 structure and the associated parameters.

### 306 **2.3 Study Site and Data**

307 We use discharge data measured at the Calawah River near Forks, WA, USA (lat-  
308 itude  $47^{\circ}57'30''$ , longitude  $124^{\circ}23'30''$ , USGS gauge 12043000). The  $334 \text{ km}^2$  catchment  
309 is illustrated in Figure 3A. The elevation ranges from about 40 m to 1200 m, and the  
310 average topographic slope of this catchment is 0.36 (Falcone, 2011). The catchment is  
311 listed in USGS Gages-II as one of the reference catchments, the least-disturbed catch-  
312 ments within the framework of broad regions (Falcone, 2011). Over 90% of the land cover  
313 is forest and about 5% is grass/shrub (see Figure 3B). The town of Forks, located near  
314 the catchment outlet, has a developed area covering about 1% of the catchment area.  
315 The land cover of some parts of the catchment has changed over time. From the three  
316 land cover maps shown in Figure 3B, a transition from grass/shrub to forest is observed  
317 at the east side of the upslope between 1985 and 2015 as forest recovers from clearing.  
318 The recovered area accounts for about 5% of the catchment area. Another logging started  
319 in the north side of the catchment around 2000 and continued, with about 5% of the catch-  
320 ment having been cleared in 2015. Correspondingly, the land cover in that region has  
321 changed from forest to grass/shrub. Regardless of the land cover change, the proportion  
322 of each land cover did not change much during 1985-2015; grass/shrub covers 4-6% of  
323 the total area, and forests cover 91-93% of the total area during the period.

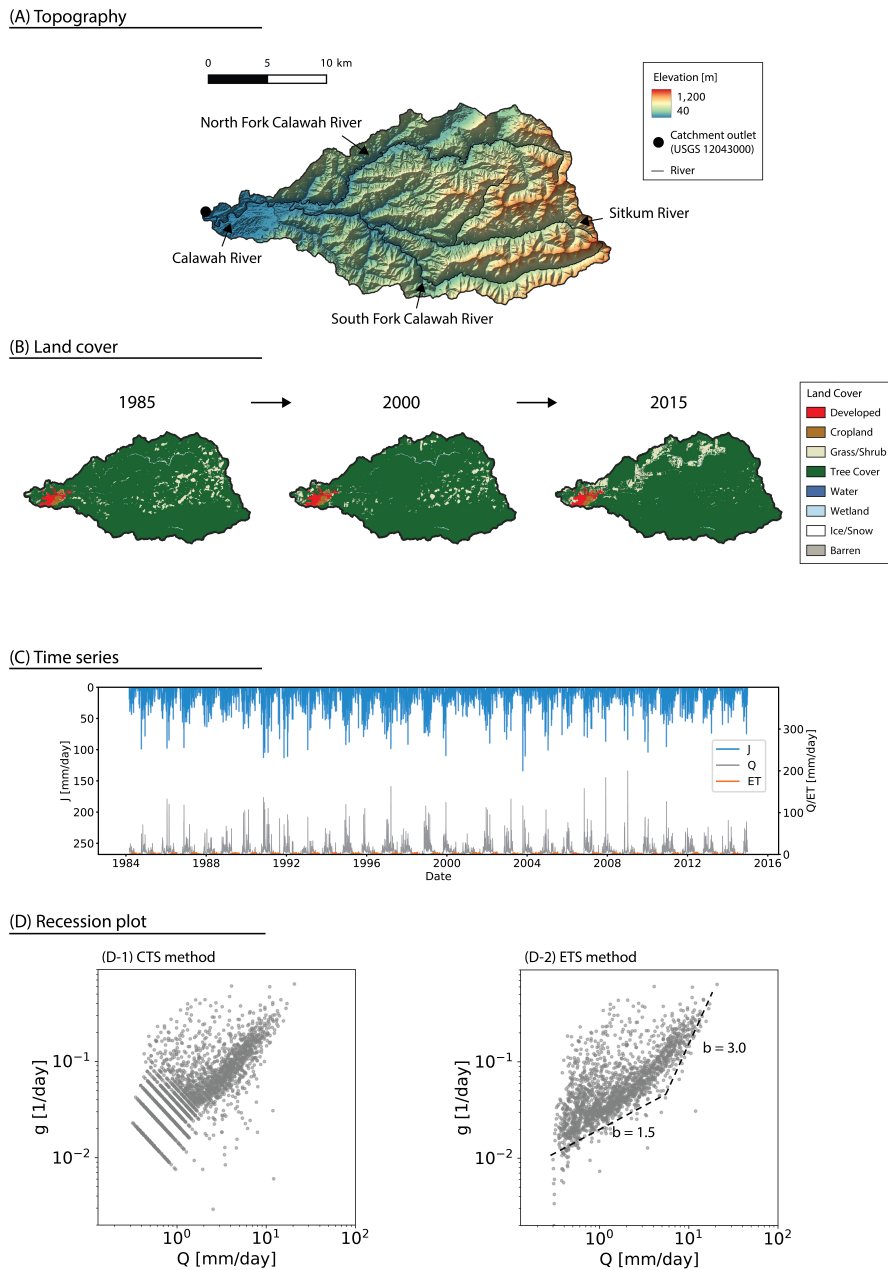

324 The CAMELS dataset (Addor et al., 2017) provides daily precipitation and poten-  
325 tial evapotranspiration rates for this catchment, derived from the 1 km resolution Daymet  
326 data (Thornton et al., 2016). The CAMELS dataset also provides an estimated actual  
327 evapotranspiration rate using the Sacramento Soil Moisture Accounting (SAC-SMA) model  
328 (Newman et al., 2015). The period of data provided in the CAMELS dataset is between

1980 and 2014, but some portions of data are missing if, for example, discharge is not measured. As a significant portion of discharge data before March 1984 is missing for this catchment, our study period is from March 1984 to December 2014. For the study period, the average precipitation rate is 3,005 mm/year and the mean discharge rate is 2,819 mm/year. The estimated actual evapotranspiration rate is 476 mm/year. Figure 3C shows the precipitation, the discharge, and the actual evapotranspiration rates. This catchment is wet with an aridity index of 0.25. The mass-balance does not close due to an overestimation of the actual evaporation rate in the SAC-SMA model (as the model underestimated discharge), but note that the recession analysis does not rely on the mass-balance and the quality of the actual evaporation time series. Also, while the actual evaporation rate is similar to that is reported for the region (Sanford & Selnick, 2013), the actual evaporation rate might be low for a forest catchment due perhaps to the underestimated precipitation rate in the Daymet data. Note that the amount of precipitation does not affect the flow recession analysis, whereas the timing of precipitation may have a limited influence on the analysis. Missing precipitation events would result in including misplaced data points in the recession plot if the precipitation event was significant enough to affect the flow recession dynamics. Nevertheless, by only using periods with decreasing discharge in the analysis, the effect of missing precipitation events that are significant enough to increase discharge can be eliminated. Note also that many studies do not use the precipitation data and rely only on discharge data when determining recession periods (e.g., Shaw & Riha, 2012; Jachens et al., 2020).

We use daily data in this study, as daily datasets are more commonly available than higher temporal resolution datasets. However, when using a daily dataset, applying the criterion  $Q \gg ET$ , that is used to estimate the catchment sensitivity function in Kirchner (2009), can exclude a lot of low flow data. Thus we do not use that criterion, and in terms of the catchment sensitivity function, our analysis can be seen as analyzing the function in which the effect of evapotranspiration is included implicitly.

## 2.4 Applied methods and model setup

We used the precipitation time series and the criterion of  $dQ/dt \leq 0$  to determine the recession period. Days with precipitation were excluded from the recession period. Periods with  $dQ/dt = 0$  were included since actual decreases in discharge might not be recorded due to the measurement resolution. We have not applied the recession

**Figure 3.** Catchment topography, land cover maps, time series, and the flow recession plots. (A) Topography of the Calawah catchment. This digital elevation map is available through the 3D Elevation Program (3DEP) managed by USGS, and its resolution is  $1/3$  arc-second. The color illustrates elevation and is shaded with the position of light source at altitude  $45^\circ$  and azimuth  $315^\circ$ . (B) Land cover maps. The LCMAP (Land Change Monitoring, Assessment, and Projection) products managed by USGS were used. (C) Time series of the precipitation  $J$ , the discharge  $Q$ , and the actual evapotranspiration  $ET$ . (D) The recession plots that were estimated using (D-1) the CTS method and (D-2) the ETS method. Note that data points with  $dQ/dt = 0$  are not shown in these log-log scale plots. The dotted lines in (D-2) are the lower envelope of (Brutsaert & Nieber, 1977) that were placed close to the lower envelope of the major data points by visual inspection.

361 event length-based criterion as we do not perform statistical analysis for each recession  
 362 event separately. We applied both CTS and ETS methods to estimate the function  $g$ .  
 363 We focus on analyzing the CTS-based estimation since our purpose is analyzing data and  
 364 because the ETS method involves data smoothing. Nevertheless, we present the ETS-  
 365 based estimation for comparison.

366 The LSTM model was constructed with the same structure as described in Figure  
 367 2. The model has two recurrent LSTM layers and the dropout layer in the middle. There  
 368 is also the dense layer after the second recurrent LSTM layer. The mean absolute error  
 369 (MAE) was used as the loss function. The training period was from March 1984 to De-  
 370 cember 2000, and the validation period was from January 2001 to December 2014. About  
 371 55% of the estimated  $g$  values were included in the training period, and another 45% of  
 372 the values were included in the validation period. The number of LSTM units in each  
 373 cell in the first layer  $n_{u,1}$  and the second layer  $n_{u,2}$  were determined using the grid search,  
 374 and the hyperparameters that minimize the MAE in the validation period were chosen.  
 375 The values tested in the first grid search were 1, 3, 5, 10, 15, 20, 30, 40, and 50. Addi-  
 376 tional values of 60, 70, 80, 90, and 100 were tested when the minimum MAE was found  
 377 at the maximum value explored in the first search. The grid search was performed for  
 378 several lengths of the past discharge trajectory: 1, 2, 3, 5, 7, and 10 days. The number  
 379 of trainable parameters  $n_p$  is determined by the model structure,  $n_{u,1}$ , and  $n_{u,2}$  as:  $n_p =$   
 380  $4(n_{u,1}^2 + n_{u,2}^2 + 2n_{u,1} + n_{u,2}(n_{u,1} + 1)) + n_{u,2} + 1$ . The Adam solver (Kingma & Ba, 2017)  
 381 was used for training, and the learning rate was 0.001. The iteration was set to stop if  
 382 the loss function of the validation set did not improve over 200 iterations. The dropout  
 383 rate was 0.5. The use of early stopping criteria and the high dropout rate are to reduce  
 384 overfitting (e.g., Srivastava et al., 2014; Prechelt, 1994). Also, the model performance  
 385 during the validation period was checked to ensure that the model performs reasonably  
 386 well outside of the training period. TensorFlow (Abadi et al., 2015) was used to imple-  
 387 ment the model.

388 Here we note that assessing the advantages of the LSTM model over simpler ML  
 389 models, such as the vanilla recurrent neural network model, is not the focus of our study.  
 390 A well-known advantage of the LSTM model over simpler neural network models is that  
 391 the LSTM can utilize longer past data without causing a problem in the parameter es-  
 392 timation, but our application might not take full advantage of the LSTM model if the  
 393 past trajectory that we need to consider to model flow recession dynamics is relatively

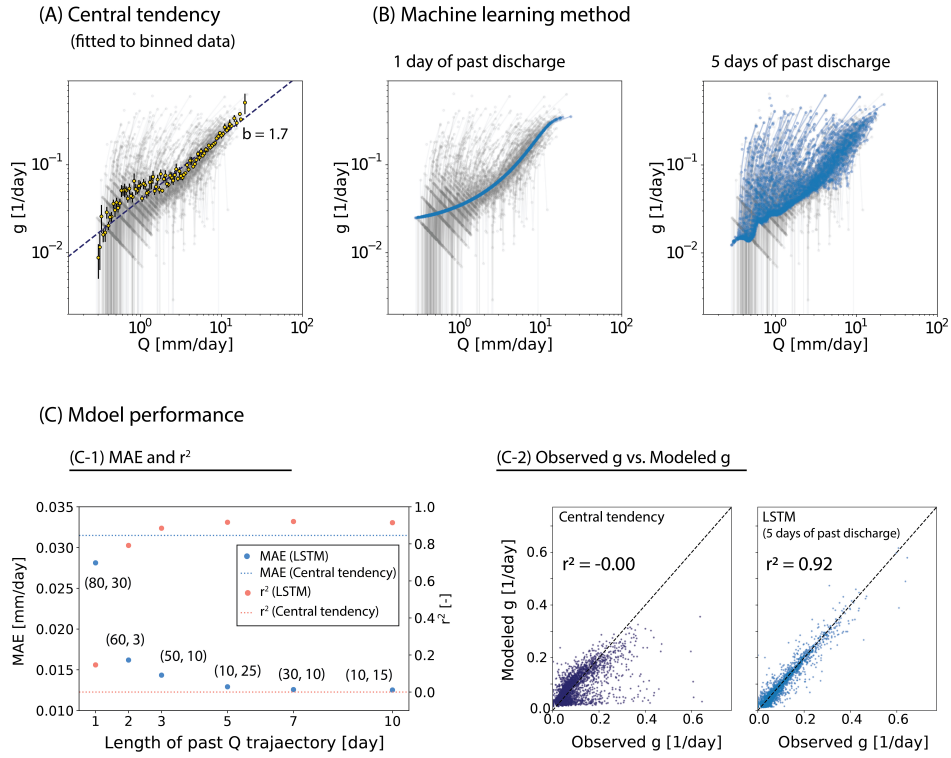

394 short. While how long the past trajectory should be to take the advantage of the LSTM  
 395 model depends on the properties of the data, there is a chance that we may implement  
 396 a more complex model than is necessary to efficiently capture the flow recession dynam-  
 397 ics. Nevertheless, there are not many additional benefits to using simpler ML models,  
 398 especially when our focus is on capturing patterns in data (and not on prediction) and  
 399 when our focus is not on interpreting the model parameters directly.

### 400 **3 Results**

401 This section reports the estimated function  $g$  and the function learned using the  
 402 LSTM model. We also show the results of using the central tendency for comparison.  
 403 Figure 3D shows the recession plots. The catchment sensitivity function  $g$  was estimated  
 404 for 3498 time steps for the CTS method and 2556 time steps for the ETS method. The  
 405 number of data estimated using the ETS method is less because of the increase of the  
 406 time step. As expected, the data points are widely scattered (Figure 3D). The CTS method-  
 407 based estimates show a diagonal pattern with its slope of -1 in the low discharge range  
 408 due to the measurement resolution. The estimation based on the ETS method does not  
 409 display the pattern as the discharge data was smoothed out. The lower envelope of Brutsaert  
 410 and Nieber (1977) appears to approximate the lower envelope of the data cloud, with  
 411  $b = 3$  for high flow and  $b = 1.5$  for low flow.

412 Figure 4A shows the fitted power functions as a measure of central tendency us-  
 413 ing the binned data. The binned data were estimated using the method suggested in Kirchner  
 414 (2009) using the CTS method-based estimation. The slope of the fitted line is close to  
 415 the slope of the lower envelope at low flow and is much lower than the trajectories of each  
 416 event that are indicated by the gray lines connecting the data points of each event. The  
 417 coefficient of determination  $r^2$  between the data points and the modeled values using the  
 418 fitted line is -0.00. Figure 4C shows that there is a structure in the model error. In the  
 419 modeled value versus the observed value plots, many dots are densely located right above  
 420 the 1:1 line, and the other dots are very sparsely located under the line. This pattern  
 421 in the plot, along with the low  $r^2$  value, means that the fitted lines do not represent the  
 422 data well.

423 The half-step ahead prediction results of the LSTM model (i.e.,  $g(t + \Delta t/2)$  es-  
 424 timated using  $Q(t)$  and its past values) are shown in Figure 4B, and the model perfor-

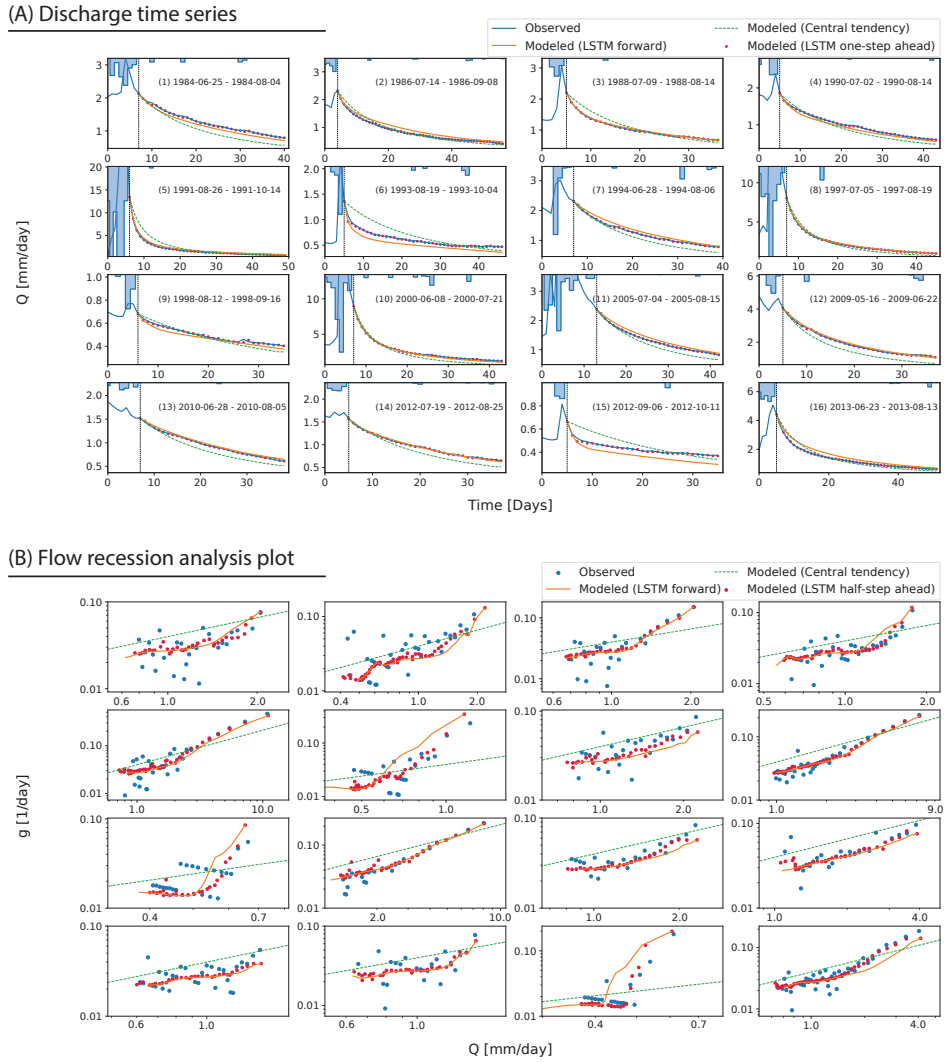

**Figure 4.** Estimated flow recession dynamics and model performance. The top panels show the estimated flow recession dynamics using (A) the central tendency and (B) the LSTM model. The grey dots are the observed data points, and the grey lines connect the points of each recession event. The yellow circles in (A) are the binned data with the error bar indicating the standard deviation of each bin. The dotted line is the power function fitted to the binned data. In (B), the blue dots are the ML model estimation and the blue lines connect the blue dots of each event. Panel (C-1) illustrates the MAE and the  $r^2$  between the CTS method-based estimation of  $g(Q)$  and the modeled  $g(Q)$  using the central tendency model and the LSTM model with several lengths of past discharge trajectory as the model input. The chosen values of  $n_{u,1}$  and  $n_{u,2}$  are displayed in the format  $(n_{u,1}, n_{u,2})$ . (C-2) illustrates the modeled  $g$  and the observed  $g$ . The dotted black lines are 1:1 lines.

425 mance is illustrated in Figure 4C. The model results are shown for different lengths of  
 426 discharge trajectories (1 day and 5 days) that were used in the function  $H$ . The LSTM  
 427 model performance was similar for both training and validation periods (e.g., with the  
 428 mean absolute error of  $0.013 \text{ day}^{-1}$  for both periods when 5 days of discharge was used),  
 429 and the illustrated LSTM results are for both periods. The similar mean absolute er-  
 430 ror for both periods indicates that overparameterization is unlikely. The plot of the mean  
 431 absolute error at each iteration during the LSTM model training also does not show any  
 432 consequences of overparameterization (see Figure S1 for the LSTM model using 5 days  
 433 of the past discharge). We only show the results estimated using the past trajectory of  
 434 discharge up to 5 days since there was no significant improvement when we increased the  
 435 number of days to more than 5 days (see Figure 4C). The chosen number of LSTM units  
 436 that minimizes the MAE for each case are also illustrated in Figure 4C.

437 The model results are similar to the pattern of the binned data when only a sin-  
 438 gle discharge value is used, but the model improves significantly as longer past trajec-  
 439 tories of discharge are used. The coefficient of determination  $r^2$  is 0.14, 0.88, and 0.92  
 440 for the model using 1 day, 3 days, and 5 days of discharge, respectively. Figure 4C shows  
 441 that the model results are significantly improved compared to the central tendency model.  
 442 In the modeled value versus the observed value plots, the dots are distributed close to  
 443 the 1:1 lines.

444 Figure 5 shows the simulated flow recession dynamics for 16 events. (Note again  
 445 that the LSTM model can simulate one-step ahead discharge  $Q(t+\Delta t)$  using the half-  
 446 step ahead  $g$ ,  $g(t+\Delta t/2)$ , as described earlier.) In this analysis, we chose events longer  
 447 than 30 days so that we can see enough recession dynamics for each event. We select events  
 448 if the condition of  $dQ/dt < 0.025 \text{ mm/day}^2$  holds for more than 30 days, assuming that  
 449 the discharge increase of  $0.025 \text{ mm/day}$  over one day is insignificant. Also, the precipitation-  
 450 based criterion was not applied. As expected, the one-step ahead prediction of  $Q$  is close  
 451 to the observed discharge. When the model is used as a forward model (updating the  
 452 model input with the modeled  $Q$  as it becomes available), the model performance de-  
 453 grades when the first few estimations are biased because the LSTM model was trained  
 454 for the prediction of the half-step ahead  $g$ . Nevertheless, the model tracks patterns of  
 455 the event trajectories in the recession plot well as they vary from event to event. (Also,  
 456 see Figure S2 that illustrates the event-to-event variation more clearly.)

**Figure 5.** Forward modeling result of the LSTM model for the 16 events. (A) The simulated discharge time series, and (B) the simulated trajectory in the recession plot. The forward model was run after the largest rain event (see the vertical dotted lines in (A)). The red dots represent the one-step ahead or the half-step ahead predictions, and the orange lines illustrate the forward model predictions.

## 4 Discussion: Learning from the machine

The results indicate that the machine has learned the non-linear hysteretic function  $H$  during the flow recession periods. But converting the machine-learned function into a human-readable format is currently a daunting task (e.g., Nearing et al., 2021). It is not easy to interpret the  $U$  and  $W$  matrices and the  $b$  vectors in a physically meaningful way. Nonetheless, our model results indicate that the hysteretic recession dynamics can be determined by the last few days of discharge (about 5 days to get  $r^2 \approx 0.9$ ). We can also investigate some machine-learned characteristics and deduce why the machine learned those features. In this study, we focus on analyzing machine-learned characteristics that we observe in the recession plot including the trajectories of each recession event illustrated in the plot as the machine-learned trajectories display patterns that were not clear in the data (see Figure 4). For the discussion, we will treat the recession plot as a phase space plot so that we can leverage terminology and methods developed to explain the trajectory of system dynamics. The result of the LSTM model using 5 days of discharge and the CTS method-based estimation is used for the following analysis. We focus on analyzing the half-step ahead estimation of  $g$  instead of the forward model estimation because the half-step ahead estimation is closer to the data (see Figure 5B). Nevertheless, most of the analyses presented in this section are still valid with the forward modeling estimation.

### 4.1 Recession plot as a phase space plot

In this discussion, we treat the recession plot as “phase space plot”. Phase space plots show dynamics of a set of state variables that describe the system state. In other words, phase space plots show (a part of) the phase space where every degree of freedom is represented as an axis in a multidimensional space. The set of state variables of a system is projected as a point in the phase space plot, and its time evolution is represented as a trajectory. Analyzing the trajectory helps understand system dynamics. For example, some systems show an “attractor” in the phase space plot, toward which a system tends to evolve (e.g., Ruelle & Takens, 1971). The phase space plot has been utilized to describe system dynamics in many fields. In classical mechanics, the position and momentum of a particle are used as state variables (e.g., Goldstein, 1980). In thermodynamics and statistical mechanics, macroscopic variables such as pressure and temperature are used as state variables, as considering states of every single particle, i.e.,

489 microstates, in a system is not feasible. For example, pressure-volume diagrams have been  
 490 viewed as describing parts of the phase space. Phase space plots have also been employed  
 491 occasionally in hydrology. While system-scale variables (macroscopic variables) of hy-  
 492 drologic system that we can measure are limited, several studies utilized phase space plots  
 493 to analyze catchment dynamics based on measurable or estimable variables (Porporato  
 494 & Ridolfi, 1997; Duffy & Cusumano, 1998; Beven & Davies, 2015). For example, Duffy  
 495 and Cusumano (1998) used the concentration-discharge plot as a phase space plot. Beven  
 496 and Davies (2015) utilized variables such as storage, discharge, and water residence time  
 497 and transit time, to construct phase space plots.

498 Discharge is a *measurable* surrogate variable that indicates a state of a catchment.  
 499 Its time rate of change (or the rate of change divided by discharge; i.e.,  $g$ ) indicates how  
 500 fast the state evolves. Thus, the recession plot can be viewed as a projected phase space  
 501 plot that illustrates a part of the phase space of a catchment. In addition, the recession  
 502 plot can be thought of as a plot showing a part of the reconstructed phase space based  
 503 on the method of time delay embedding. Takens' delay embedding theorem asserts that  
 504 information about the hidden states (unobservable states) of a dynamical system can be  
 505 contained in a time series of an output and that the phase space can be reconstructed  
 506 using multiple delayed time series of the output (Takens, 1981). For example, if discharge  
 507  $Q(t)$  is used as the output,  $Q(t)$  and its time-delayed variables,  $Q(t-\Delta\tau)$ ,  $Q(t-2\Delta\tau)$ ,  
 508  $\dots$ ,  $Q(t-(k-1)\Delta\tau)$ , where  $k$  is the embedding dimension and  $\Delta\tau$  is the time delay,  
 509 can be used as state variables to reconstruct the phase space (Porporato & Ridolfi, 1997).  
 510 When  $k$  and  $\Delta t$  are chosen appropriately, the reconstruction preserves the properties of  
 511 the dynamical system that do not change under smooth coordinate changes (i.e., diffeo-  
 512 morphisms); For example, the attractor in the reconstructed phase space is topologically  
 513 equivalent to the actual attractor, meaning that the trajectory shown in the reconstructed  
 514 phase space can be used to understand system dynamics. Plotting the dynamics of  $Q(t)$   
 515 and  $dQ(t)/dt$  or  $Q(t)$  and  $g(t)$  is similar to that of  $Q(t+\Delta t/2)$  and  $Q(t-\Delta t/2)$  since  
 516  $Q(t)$  and  $dQ(t)/dt$  (or  $g(t)$ ) have all the information necessary to estimate  $Q(t+\Delta t/2)$   
 517 and  $Q(t-\Delta t/2)$ . In that sense, the recession plot is similar to a reconstructed phase  
 518 space with the embedding dimension of two. In our case, the time delay is one day.

519 We note here that suggesting what variables to use to construct (or reconstruct)  
 520 a phase space that fully describes the system state is not a topic of this study. We only  
 521 argue that the recession plot, that has been utilized very frequently in hydrology, has

522 a certain similarity to the phase space plot and that we may be benefited by analyzing  
 523 the recession plot using methods and concepts developed to explain system dynamics  
 524 using the phase space plots. The embedding dimension of two provides a convenient way  
 525 of visualization perhaps without losing too much information. While the LSTM model  
 526 result showed that 5 days of past discharge is needed to capture the flow recession dy-  
 527 namics in the study catchment,  $Q(t-\Delta t/2)$  would be a dominant component in deter-  
 528 mining  $Q(t+\Delta t/2)$  or  $g(t)$ . In what follows we will focus on analyzing the system dy-  
 529 namics shown in the recession plot.

## 530 4.2 The attractor and hysteresis in the phase space plot

531 A characteristic that we observe in the phase space plot is that there is an area where  
 532 the LSTM estimated points are densely located. Figure 6A shows the Gaussian kernel  
 533 density estimation  $\hat{f}_h(Q, g)$  (e.g., Silverman, 1986) illustrated by the color of each point.  
 534 Scott's method (Scott, 1992) was used to calculate the bandwidth of the kernel. The yel-  
 535 low and green area is where the points are densely located. The dense area is a region  
 536 where the catchment has spent a significant amount of time, meaning that the flow dy-  
 537 namics of the dense area are slow or that the flow dynamics associated with that area  
 538 are repeated frequently. The dense area can be divided into two parts according to its  
 539 slope in the plot: the lower dense area with low slope (mainly the yellow area) and the  
 540 upper dense area with high slope (mainly the green area).

541 An event trajectory shows that the flow dynamics in the lower dense area ( $\hat{f}_h >$   
 542 0.35) is slow. The red line in Figure 6A is the LSTM model learned trajectory of an event  
 543 from Sep. 1, 1991 to Oct. 14, 1991, which ended up in the yellow area. The event spent  
 544 about half of its time in the yellow area (see the discharge time series in Figure 6B), while  
 545 the line length of trajectory in the recession plot is much shorter inside the yellow area  
 546 than the line length of trajectory of the earlier period. Note that the event trajectory  
 547 in the yellow area also can be estimated using the ETS method, but is not easy to es-  
 548 timate using the CTS method-based estimation due to greater noise (see Figure 6C). Note  
 549 also that several parts of the trajectory (the red line) are indicated by dashed lines when  
 550 the associated period is not determined as a recession period. According to the criteria  
 551 for determining recession periods that we applied, this event was divided into three re-  
 552 cession events due to a very small precipitation event (0.83 mm/day) and two small in-  
 553 creases in discharge (about 0.02 mm/day increase over one day; see Figure 6B). How-

554 ever, looking at the discharge time series, it makes sense to treat the entire event as a  
555 single recession event. The precipitation event appears to be too small to affect the flow  
556 dynamics. The increases at two times are very small, and since the cause of the small  
557 increases is not clear, it seems better not to use the two small increases to determine the  
558 recession period.

559 The yellow area is not only the area where the flow dynamics are slow but also the  
560 area that is often explored. Figure 6E shows that all 16 recession events over 30 days,  
561 which were selected previously, converge to the yellow area and then move along that  
562 area towards the lower-left corner. The same pattern is also observable in the forward  
563 model result (see Figure S2). It means that the yellow area behaves like an “attractor”,  
564 where all dynamics converge to that area and then move within that area, unless those  
565 dynamics are pushed away from it by external forcings. (See Beven and Davies (2015)  
566 for more discussion on the attractor in catchment hydrology.) This attractor will be called  
567 the “catchment flow attractor” because the attractor is a signature of catchment scale  
568 flow dynamics. (Note again that we only focus on the flow recession dynamics in this study  
569 and that exploring the potential existence of the catchment flow attractor in the rising  
570 limb of discharge is left for future research.) The dynamics in the catchment flow attrac-  
571 tor are expected to be equilibrated at a fixed point of zero flow as a point of “maximum  
572 entropy” (Beven & Davies, 2015). This state was not explored in this catchment because  
573 external forcing (e.g. precipitation) constantly pushes the system away from the point  
574 of maximum entropy.

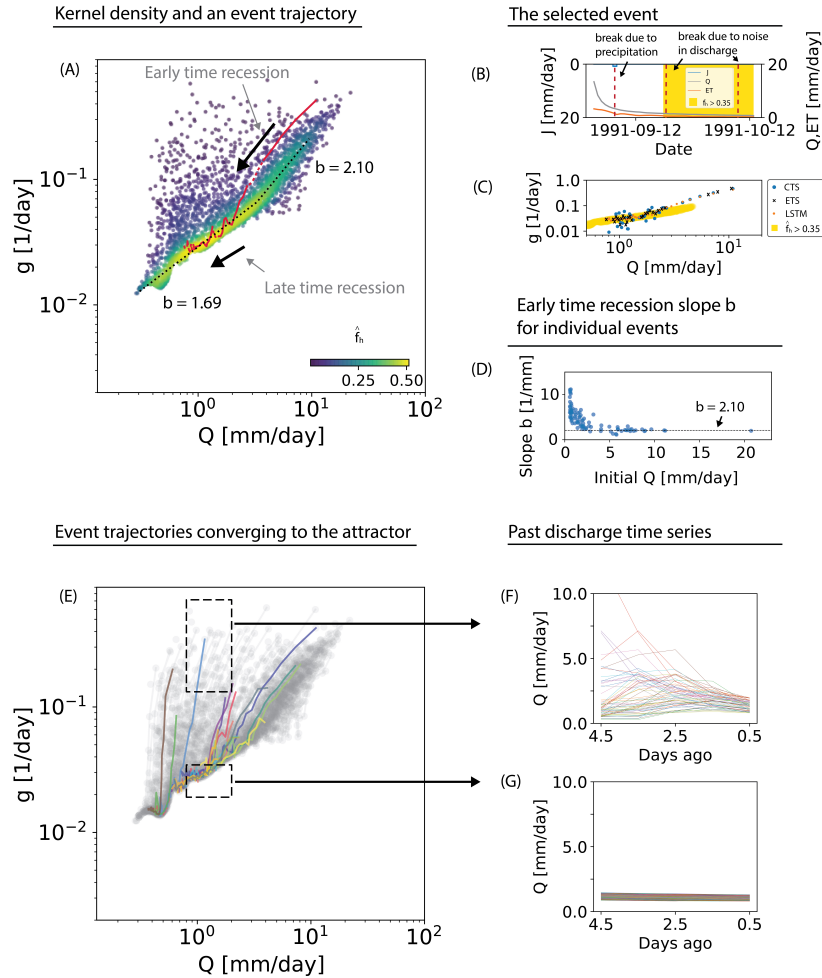

575 The dense area is where the most characteristic information about catchment scale  
576 recession dynamics exists. The area is a better representation of the ensemble of many  
577 recessions than the measure of central tendency and the lower envelope of Brutsaert and  
578 Nieber (1977). While the binned data capture the pattern of the dense area (see Figure  
579 4A), the binned data are places above the dense area because it considers all data points.  
580 The situation is similar for the ML result with insufficient length of the past discharge.  
581 The full consideration results in the structure of the errors in the modeled  $g$  versus ob-  
582 served  $g$  plot (Figure 4C), and the error in the forward simulation using the central ten-  
583 dency model (Figure 5). While the performance of the central tendency model can be  
584 improved when some data points are filtered out before fitting the line (e.g., filtering out  
585 the first few days of data after each rain event and thus focusing more on the late time  
586 dynamics and the attractor), it certainly reduces the information content in data and

587 neglects the hysteretic dynamics. The method of Brutsaert and Nieber (1977) seems to  
 588 fit the dense area to some extent (see Figure 3). However, we lack a method to fit the  
 589 lower envelope objectively (e.g. Jachens et al., 2020). Furthermore, the upper part of  
 590 the lower envelope with  $b = 3$ , which is predicted by the Boussinesq model, is much steeper  
 591 than the slope of the upper dense area.

592 The dense area, the area we define here as the area with  $\hat{f}_h > 0.2$  based on a vi-  
 593 sual inspection, can be parameterized to describe the flow recession dynamics within the  
 594 area. A function consisting of two linear lines (in log-log space) can be fitted to the data  
 595 points located in the dense area. The function can be written as:  $\ln g = \max(a_1 + (b_1 -$   
 596  $1) \ln Q, a_2 + (b_2 - 1) \ln Q)$ . The crossover between the two lines occurs at  $Q^* = (a_2 -$   
 597  $a_1)/(b_2 - b_1)$ . The lower line fits the catchment flow attractor with  $b = 1.69 \pm 0.00$   
 598 up to  $Q = 3.29$  mm/day (see the black dotted line in Figure 6A). The value is simi-  
 599 lar to that of the late time dynamics of the Boussinesq model ( $b = 1.5$ ). The slope of  
 600 the upper line is  $b = 2.10 \pm 0.02$ . This value is smaller than the value of early time  
 601 recession of the Boussinesq model ( $b = 3$ ). The slope  $b = 2.10$  is similar to the me-  
 602 dian value of 2.0 which is derived from the event-based analysis for 39 catchments in the  
 603 USA that are not affected by anthropogenic activities (Biswal & Marani, 2010). (Note  
 604 that more objective or sophisticated parameterization schemes to fit the dense area, such  
 605 as using the modal linear regression (Yao & Li, 2014), applying a variable threshold for  
 606  $\hat{f}_h$  over  $Q$ , or using a higher-order polynomial in the log-log space, might be applicable  
 607 but are not employed in this study.)

608 Based on the trajectory of each event in the recession plot and the attractor, we  
 609 can define “early time” recession and “late time” recession for each event. The early time  
 610 recession is until the trajectory converges to the attractor, and the late time recession  
 611 is after the trajectory converges to the attractor (see Figure 6A). Figure 6G shows that  
 612 the attractor consists of the late time recession in that there were no increases in the re-  
 613 cent past discharge data, while Figure 6F shows that above the attractor, there were in-  
 614 creases in the discharge data of the recent past. This definition has an important dif-  
 615 ference from the original definition based on the Boussinesq model result discussed ear-  
 616 lier. Our definition is based on data and the characteristic extracted from data and ap-  
 617 plies for each event trajectory, whereas the original definition is based on the process-  
 618 based model and when describing data, it applies to the lower envelope of data.

**Figure 6.** Learning from what the machine learned. (A) Kernel density estimation at each data point. Density is displayed in colors from yellow (dense) to blue (sparse). The red line is the trajectory of the events from September 1, 1991 to October 14, 1991. The line is a solid line during the periods that are determined as a recession period. Otherwise, it is a dashed line. The black arrows indicate the direction of the flow recession dynamics in the plot, and the black dashed lines are the power functions that are fitted to the dense area ( $\hat{f}_h > 0.2$ ). (B) Time series of the precipitation, the discharge, and the actual evapotranspiration during the event. If we use the recession period determination criteria discussed in the text, this event is divided into three events, and the vertical dotted lines show the timing of the division. The yellow area represents the period during which the event moves within the yellow area ( $\hat{f}_h > 0.35$ ) shown in (A). (C) Data points of the event that are estimated using several methods. (D) The fitted early time recession slope  $b$  for the events that converged to the attractor as a function of the initial discharge at recession. (Note that only events that have more than three data points in the early time recession were used.) (E) LSTM model-learned trajectories of all events longer than 30 days. (F) 5 days of the past discharge for the data contained in the upper box in (E), and (G) 5 days of the past discharge for the events contained in the lower box in (E).

619 The early time recession dynamics are, in general, similar to the dynamics reported  
 620 in the event-based analysis. There is large event-to-event variability. As Jachens et al.  
 621 (2020) reported, the recession event with lower initial discharge tends to have higher  $b$   
 622 values (see Figure 6D). At which discharge values a recession event converges to the at-  
 623 tractor tends to vary from event to event but with a trend: recession events with lower  
 624 initial discharge tend to converge to the attractor at lower discharge values. Furthermore,  
 625 the early time trajectories are mostly convex similar to the result of Tashie et al. (2020).  
 626 An important difference we found in the study catchment is that, as opposed to the claim  
 627 of Tashie et al. (2020), only the early time trajectory is convex, but the entire recession  
 628 event trajectory is concave unless the event trajectory is forced away prior to its con-  
 629 vergence to the catchment flow attractor by external forcings. The event-to-event vari-  
 630 ability of the early time recession dynamics are reduced for the events with high peak  
 631 discharge values, resulting in the upper dense area.

632 These results would suggest that the analysis of the curvature of event trajectory  
 633 is sensitive to two factors. First, it is sensitive to the  $-dQ/dt$  estimation method and  
 634 the recession event determination criteria. Tashie et al. (2020) used the CTS method to  
 635 estimate  $-dQ/dt$  and used the criteria of decreasing both  $Q$  and  $-dQ/dt$  for more than  
 636 5–7 consecutive days to determine recession periods. Thus, it is possible that the early  
 637 time dynamics is treated as one event, and the late time dynamics is treated as another  
 638 event (which is mostly linear in the plot) or not considered as a recession event due to  
 639 the noisy CTS method-based estimation (e.g., see the previous discussion about the Septem-  
 640 ber 1991 - October 1991 event). Second, it is sensitive to precipitation events. As we de-  
 641 scribed earlier, precipitation events can push the dynamics away from the catchment flow  
 642 attractor before a trajectory converges to the catchment flow attractor. When this hap-  
 643 pens frequently (e.g., in wet catchments), usual event-based analysis can place more weight  
 644 on the early time dynamics than the late time dynamics.

### 645 **4.3 Attractor and the master recession curve**

646 The existence of the catchment flow attractor implies that, at some point in reces-  
 647 sion, multiple time scale dynamics may reduce to slower dynamics that are similar for  
 648 all events. The slow dynamics in the catchment flow attractor can be described using  
 649 the fitted line. The function  $g$  decreases with decreasing  $Q$  approximately following the  
 650 power function  $g = aQ^{b-1}$ , where  $b = 1.69$  in this case. When  $g$  is the power func-

**Figure 7.** The attractor as the master recession curve. The thin lines illustrate the discharge time series of all recession events longer than 8 days. The thin lines are shifted over time from right to left until it meets the parameterized master recession curve (the thick dashed line). The parameterized master recession curve was determined using Equation 4 with the parameters that are estimated based on the CTS method estimation and the LSTM model using the past 5 days of discharge. The subset figure shows the parameterized master recession curve (the dotted line) and the time-shifted discharge time series of the previously selected 16 events (the solid line).

tion of  $Q$  (i.e.,  $g = aQ^{b-1}$  and  $-dQ/dt = aQ^b$ ), the flow recession in the catchment  
 flow attractor can be written as (e.g., Rupp & Woods, 2008):

$$Q(t) = (Q_0^{1-b} + a(b-1)t)^{1/(1-b)} \quad (4)$$

where  $Q_0$  can be chosen as discharge at a time when the system dynamics converge  
 to the catchment flow attractor, and  $t$  is the time lapse since the system converges to  
 the catchment flow attractor. When  $b \rightarrow 1$ ,  $Q(t) = Q_0 e^{-a/t}$ , and the catchment be-  
 haves like a linear reservoir. When  $b > 1$ , the tail of the discharge time series is heav-  
 ier than the exponential decay. Figure 7 illustrates that equation (4) with the estimated  
 parameters captures the late time flow recession dynamics of each recession event that  
 is longer than 8 days during the study period. The duration criterion was used to filter  
 out as many events as possible that did not converge to the attractor due to precipita-  
 tion events that occur before the trajectory of the recession event converges to it.

662 The curve represented by equation (4), that we estimated based on the parame-  
663 terized catchment flow attractor, is indeed the master recession curve. The term “mas-  
664 ter recession curve” was coined in Nathan and McMahon (1990) and introduced as a catch-  
665 ment characteristic that represents the most frequent low flow recession dynamics. The  
666 master recession curve estimated using the LSTM model result and the additional fit-  
667 ting is an ensemble of the late recession dynamics that can be thought of as a central  
668 tendency of the dynamics. The master recession curve has been estimated and discussed  
669 in many catchments (e.g., Nathan & McMahon, 1990; Lamb & Beven, 1997; Fiorotto &  
670 Caroni, 2013), but this is the first to derive a representation as an attractor that over-  
671 comes the variations from event to event without convergence (e.g., Tashie et al., 2020).  
672 Our results suggest that this may be the result of combination of the noise in data and  
673 the criteria for defining the recession periods that make it hard to recognize the master  
674 recession curve from plots of individual recessions. For the catchments where the mas-  
675 ter recession curve exists, we can expect that the attractor would exist in the recession  
676 plot and that each event trajectory converges to the attractor unless pushed away from  
677 the attractor due to external forcings. Thus, care must be taken when analyzing the re-  
678 cession plot especially for the low discharge range.

679 We suspect that in most humid catchments and if there are low flow periods a mas-  
680 ter recession curve exists, and thus the ML tool should be able to identify this catchment  
681 characteristic from recession analysis, as demonstrated here. For catchments where the  
682 seasonality of evapotranspiration affects the flow recession dynamics significantly, the  
683 shape of the attractor may exhibit seasonality. The ML tool might still be able to iden-  
684 tify the seasonality as it utilizes the past trajectory of discharge. In addition, we spec-  
685 ulate that in most semi-arid to arid regions, the attractor will be harder to identify, as  
686 recessions typically are short-lived since the runoff is mainly overland flow (e.g., Dunne,  
687 1983) and rapid lateral subsurface flow (Beven, 2002). It is an interesting research ques-  
688 tion what hysteretic system dynamics can be discovered in these catchments and what  
689 controls the recession.

#### 690 **4.4 Process-based interpretation**

691 While we did not attempt to provide detailed physical interpretation based on process-  
692 based models, we can still infer some processes that might have resulted in the dynam-  
693 ics we observed in the phase space plot and Figure 7. The event to event difference of

694 the early time recession, i.e., the dynamics before converging to the attractor, might ex-  
695 ist due to the difference in the initial condition and boundary conditions (e.g., external  
696 forcings, including precipitation and snowmelt, and consequent patterns of storage in the  
697 catchment). Differences in the initial condition and the boundary condition would also  
698 result in different hydrologic connectivity that could affect to flow recession dynamics.  
699 Those conditions would show seasonality, meaning that the event-to-event variability of  
700 the early time dynamics may also be dependent on evapotranspiration rates and season-  
701 ality. For example, most of the hysteresis is observed in dry seasons (see Figure S3). Some-  
702 time later the dynamics of each event converge to the attractor, as the spatial distri-  
703 bution of celerity that controls discharge could be uniquely characterized by the value  
704 of discharge at that time. The impact of the seasonality in the catchment scale evapo-  
705 transpiration rate on the shape of the attractor seems negligible in this catchment (see  
706 Figures S3 and S4). However, we do not rule out a possibility that evapotranspiration  
707 from wet areas (e.g., riparian areas) may affect the shape of the attractor without caus-  
708 ing time-variability in it.

709 The contrasting slope of each recession trajectory in the recession plot where it is  
710 high during the early time and is low during the late time may also indicate some pro-  
711 cesses. During the early recession, the discharge decreases at a faster rate. This may be  
712 due to the continuous deactivation of some fast flow pathways, such as overland flow and  
713 macropore flow, rapid reduction in transmissivity with lower storage, and rapid contrac-  
714 tion of variable source areas. For the late time dynamics, we hypothesize that most of  
715 the fast flow paths were already deactivated, the contraction of the variable source area  
716 is slow, and the flow dynamics are largely dominated by subsurface flow and perennial  
717 stream flow, resulting in low  $g$  values. During the late time, the Boussinesq model re-  
718 sult of the slope of the trajectory is not far from the slope of the parameterized attrac-  
719 tor, indicating that the Boussinesq model may be applicable to explain the late time dy-  
720 namics.

721 It might be worth noting here that the attractor we defined does not seem to change  
722 over time during the study period, while the land cover has changed to some extent mostly  
723 as a result of logging. The effect on the shape of the recession part of hydrograph seems  
724 negligible based on our analysis as the late time recession dynamics of each recession event  
725 can be approximated by the estimated master recession curve (see Figure 7 where all avail-  
726 able data are plotted; see also Figure S4 where data for three periods, 1984-1993, 1994-

2003, and 2004-2014, were plotted in the same way used to construct Figure 7). Furthermore, the model performance is similar for the training period (March 1984 to December 2000) and the validation period (January 2001 to December 2014) with low mean absolute error for both periods. While there are many studies that show that logging significantly impacts discharge (e.g., Moore & Wondzell, 2005), their implication to our study is unclear. Those studies mostly focus on analyzing small headwater catchments where a significant portion of the catchment is logged, and those studies mostly focused on analyzing the quantity of discharge (e.g., increasing discharge and decreasing evaporation at much larger time scale such as month or annual) and the peak flow rather than the shape of the recession part of hydrograph. Nevertheless, based on studies that show the effect of evapotranspiration on the low flow dynamics (e.g., Szilagyi et al., 2007), one may expect to observe the effect of logging on the shape of the attractor. As potential reasons for no significant temporal variation of the attractor in our study catchment, we can hypothesize that: 1) the scale of this catchment is large enough compared to the area of the land use change; Only about 5% of the catchment has been recovered during the period, and about another 5% of the catchment has been logged during about the latter half of the study period according to the LCMAP data, 2) in this catchment, the shape of the recession hydrograph might not be affected much by the land cover change and the associated change in water partitioning, but other factors such as geomorphologic structure, soil hydraulic properties, and geology that were not changed significantly during the study period dominantly determine the shape.

#### 4.5 Estimating storage-discharge relationship using the attractor

The catchment flow attractor, which represents the most frequent low flow recession dynamics during the period of record used in this study, can be utilized to estimate the hysteretic active storage-discharge relationship. In previous studies, the catchment sensitivity function that is estimated as a central tendency has been used to estimate the storage-discharge relationship (e.g., Kirchner, 2009; Dralle et al., 2018), neglecting the hysteresis in the storage-discharge relationship. The existence of the attractor implies that the hysteresis in the storage-discharge relationship is not detectable from the discharge data after each recession event converges to the attractor, while the hysteresis is detectable before the system dynamics converge to the attractor. It means that a non-hysteretic storage-discharge relationship would sufficiently capture the catchment

**Figure 8.** The recession plot and the corresponding storage-discharge relationship. (A) Two event trajectories in the recession plot are illustrated by the red and the blue lines. The solid grey line shows the parameterized attractor, and the dashed grey line shows the parameterized upper dense area. (B) The corresponding active storage-discharge relationship. The marker ‘X’ in both (A) and (B) indicates  $g$  and the active storage at a low flow condition at which the storage is set to zero. The solid grey line and the dashed grey line illustrate the relationship estimated using the parameterized attractor and the parameterized upper dense area.

759 dynamics during recession periods inside the attractor. Using the non-hysteretic part of  
 760 the relationship, the hysteretic storage-discharge relationship can be estimated in terms  
 761 of drying scanning curves if we calculate the storage using the mass-balance backward  
 762 in time starting from the attractor.

763 Figure 8 shows the (relative) active storage-discharge relationship for the two events  
 764 (the 1998 July - September event and the 2013 June - August event that are shown in  
 765 Figures 5 and 6) estimated considering the discharge time series; i.e.,  $dS/dt = -Q$ . The  
 766 relative active storage was estimated from the point marked by ‘X’ with the initial con-  
 767 dition of zero relative storage. The storage-discharge relationship in Figure 8 shows that  
 768 the event trajectories overlap at a low flow condition, when the system flow dynamics  
 769 move inside the attractor. The overlapped trajectory can be captured by the storage-  
 770 discharge relationship that is estimated using the parameterized  $g(Q)$  for the attractor  
 771 (see Figure S5). While we estimated the storage from the certain point in the example,  
 772 it is straightforward to generalize it by estimating the storage-discharge relationship as-  
 773 sociated with the attractor first and then calculate the storage backward in time from  
 774 the attractor. The storage-discharge relationship associated with the upper dense area

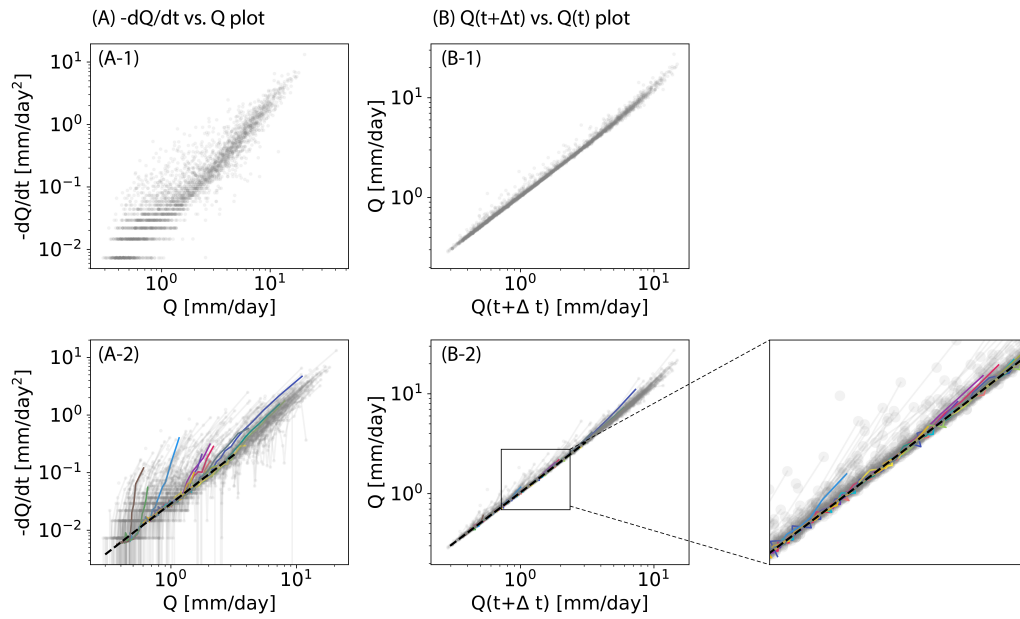

775 can also be used to estimate the hysteretic storage-discharge relationship at high flow  
776 conditions.

777 It is also possible to estimate the relative “total” storage considering  $ET$  from an  
778 initial condition; see Figure S5. The figure implies that another attractor may be found  
779 using  $g = (dQ/dt)/(-Q - ET)$  (instead of using  $g = (dQ/dt)/(-Q)$ ) and that the at-  
780 tractor may be utilized to estimate the hysteretic (relative) total storage-discharge re-  
781 lationship. Note again that the denominator of  $g$  is  $dS/dt$  in its full formulation, and the  
782 form used in (1) neglects the effect of  $ET$  in the storage variation. While this method  
783 is, in part, based on the mass-balance, it is different from the traditional mass-balance  
784 approach that estimates the relative total storage starting from a fixed initial time. The  
785 traditional method can result in the drift of storage over time when the mass-balance  
786 is not closed and the uncertainty in the estimated storage accumulates over time. In the  
787 method using the attractor, the initial time of storage calculation is the most recent time  
788 when the system dynamic is in the attractor, reducing the uncertainty. It is more likely  
789 that this attractor may exist under the water-limited condition where  $ET$  is limited by  
790 water availability. We leave a further discussion about the effect of  $ET$  on the catchment  
791 sensitivity function and the total storage-discharge relationship for future study.

#### 792 **4.6 Attractor in other phase space plots**

793 In this last subsection of discussion, we briefly introduce other phase space plots  
794 and how the attractor and the trajectory of system dynamics appear in the plots. Some  
795 plots that we previously discussed can be treated as a phase space plot. For example,  
796 the storage-discharge plot is a phase space plot, and where the event trajectories over-  
797 lap (e.g., the storage-discharge relationship approximated using the parameterized  $g(Q)$   
798 for the attractor in the recession plot) is the attractor in the storage-discharge relation-  
799 ship (see Figure 8 and Figure S5). Figure 7 can also be thought of as a phase space plot,  
800 while unlike other phase space plots, a reconstruction of data (i.e., shifting event discharge  
801 time series) is required to produce the plot. In the phase space plot, the master reces-  
802 sion curve is the attractor.

803 In addition, the plot of  $Q(t+\Delta t)$  vs.  $Q(t)$  and the other type of the recession plot,  
804  $-dQ/dt$  vs.  $Q$  plot, are phase space plots. As expected, the  $-dQ/dt$  vs.  $Q$  plot shows  
805 information in a similar way to the  $g$  vs  $Q$  plot (see Figure 9A), while the hysteretic dy-

**Figure 9.** Other phase space plots. (A)  $-dQ/dt$  vs.  $Q$  plot and (B)  $Q(t + \Delta t)$  vs.  $Q(t)$  plot. The top figures show the data during the flow recession periods. The bottom figures show the trajectory of each recession event (the grey lines) and the trajectory of the sixteen events that were selected previously (the lines colored in the same way to Figures 7 and 8). The black dashed lines illustrate the parameterized attractor from the  $g$  vs.  $Q$  plot using the LSTM model result.

806 namics are displayed more clearly in the  $g$  vs  $Q$  plot. All findings that we draw from the  
 807  $g$  vs  $Q$  plot can be observed in the  $-dQ(t)/dt$  vs  $Q$  plot. For example, while the attrac-  
 808 tor is not clearly visible in the  $-dQ(t)/dt$  vs  $Q$  plot generated by data (Figure 9A-1),  
 809 the machine-learned trajectories show the attractor clearly (Figure 9A-2).

810 Figure 9B shows the plot of  $Q(t+\Delta t)$  vs.  $Q(t)$ . This plot was introduced in Langbein  
 811 (1938) and discussed in Linsley et al. (1958) and Brutsaert (2005). They described that  
 812 the lower envelope and the upper envelope can be used to characterize the slowest re-  
 813 cession and the fastest recession dynamics, respectively. We discussed in section 4.1 that,  
 814 this plot can be used as a phase space plot and, in theory, would show the same infor-  
 815 mation compared to the other phase space plots we discussed. However, there is a no-  
 816 table difference in the pattern of data shown in this plot compared to the pattern in other  
 817 phase space plots: The area where the data points are densely located is clearly displayed  
 818 over the entire discharge range. This is because the derivative of discharge, that induced  
 819 the noise in the recession plot, is not involved. There is noise in the discharge data that  
 820 creates a zigzag pattern in the event trajectory (see Figure 9B-3), but the noise does not  
 821 appear large enough to obscure the lower envelope. The parameterized attractor from  
 822 the  $g$  vs.  $Q$  plot can be displayed in this plot using:  $Q(t + \Delta t) = (Q(t)^{1-b} + a(b -$   
 823  $1))^{1/(1-b)}$ , that is derived using equation (4), and the parameterized attractor fits the  
 824 dense area for the low discharge range ( $< 3.29$  mm/day; see Figure 9B-2). It might be  
 825 tempting to parameterize the attractor from the  $Q(t+\Delta t)$  vs.  $Q$  plot as the dense area  
 826 displays clearly unlike the data represented in the recession plot, but care must be taken.  
 827 While the shape of the dense area for the low discharge range looks almost linear, im-  
 828 plying that  $b = 1$  in  $-dQ/dt = aQ^b$ , the  $b$  value estimated from the  $g$  vs  $Q$  plot is 1.69.  
 829 The parameterized attractor with  $b = 1.69$  looks almost linear in this plot, illustrat-  
 830 ing that the non-linearity is not clearly visible. (See Figure S6 for the consequence of us-  
 831 ing the  $b = 1$  to characterize the low flow dynamics). In addition, the degree of hys-  
 832 teresis is suppressed in this plot compared to other plots that we discussed; however, it  
 833 does not mean that the hysteresis is negligible as we discussed in preceding sections (e.g.,  
 834 see Figures 6 and 7).

835 In summary, those plots show the same information in a different way, and some  
 836 information is displayed more clearly in one plot than the others. The hysteretic flow  
 837 recession dynamics are shown more clearly in the  $g$  vs.  $Q$  plot or in the  $-dQ/dt$  vs  $Q$   
 838 plot than the plot of  $Q(t+\Delta t)$  vs.  $Q(t)$ . The existence of the attractor can be more clearly

839 inferred from the  $Q(t+\Delta t)$  vs  $Q(t)$  plot. It might be worthwhile to examine other phase  
840 space plots, e.g., Poincaré section of Porporato and Ridolfi (1997, 2003) (see Figure S7),  
841 if there is additional information about catchment dynamics that we could learn. For  
842 example, some phase space plots, such as the Poincaré section, include the rising limb  
843 of discharge data. What we have described in this study can be used to explain the flow  
844 recession dynamics in the plot (as described in Figure S7), and there may be room for  
845 better understanding the rising limb of discharge by utilizing such a plot. Also, there still  
846 might be unexplained patterns in the recession data which may be displayed more clearly  
847 in other phase space plots.

## 848 5 Conclusions

849 The flow recession analysis has been presented as a tool to understand catchment  
850 scale flow dynamics and catchment properties (e.g., Troch et al., 2013). However, there  
851 are seemingly contrasting methods of extracting information from the flow recession plot  
852 ( $Q$  versus  $-dQ/dt$  or  $(-dQ/dt)/Q$ ). Traditional methods use the lower envelope to cap-  
853 ture the ensemble characteristics of many recessions (Brutsaert & Nieber, 1977), or use  
854 a fitted function to entire data points as a measure of centrality (Vogel & Kroll, 1992;  
855 Kirchner, 2009). In contrast, recent studies highlight the importance of the event scale  
856 analysis and have questioned the use of the lower envelope and the measure of central-  
857 ity (Jachens et al., 2020; Tashie et al., 2020).

858 Based on the machine learning model results, we emphasize the importance of an-  
859 alyzing both the ensemble characteristics and the event scale dynamics. The machine  
860 learning model developed in this study, the Long Short-Term Memory (LSTM) model  
861 using 5 days of past discharge, captures both the ensemble characteristics and the event  
862 scale dynamics of the Calawah catchment. The LSTM model results indicate that the  
863 early time dynamics, which are sensitive to initial conditions, lead to the hysteretic tra-  
864 jectories of system dynamics that appear in the recession plot. Analyzing such hysteretic  
865 trajectories (event scale trajectories of the early time dynamics) is the focus of previous  
866 event scale analysis studies (Jachens et al., 2020; Tashie et al., 2020). The model results  
867 further show that the trajectories of system dynamics converge to an attractor, the catch-  
868 ment flow attractor, unless pushed away from the attractor due to external forcings. The  
869 early time recession dynamics of large events also share similar trajectories (i.e., the up-  
870 per dense area determined in the Gaussian kernel density analysis), perhaps because those

871 dynamics for larger events are less sensitive to initial conditions. The catchment flow at-  
872 tractor and the upper dense area represent ensemble characteristics of many recessions.  
873 We also briefly illustrated that the catchment flow attractor can be utilized to estimate  
874 the drying part of a hysteretic storage-discharge relationship. The active storage esti-  
875 mated in this study might be affected by evapotranspiration because we did not apply  
876 the criterion of  $Q \gg ET$ . The criterion was not applied mainly because we used the  
877 daily dataset and since applying the criterion would remove a significant portion of the  
878 dry season data. However, the shape of the attractor does not show seasonal variation,  
879 implying that the effect of the seasonal variation of evapotranspiration on the attractor  
880 is not significant in the study catchment. (Note that the effect of evapotranspiration dur-  
881 ing the recession period may appear more clearly at low flow conditions; see Szilagyi et  
882 al. (2007).) One way to confirm the effect of evapotranspiration on the active storage  
883 and the catchment sensitivity function would be using hourly data. Applying the con-  
884 dition of  $Q \gg ET$  to hourly data could avoid filtering out too much of dry season data.  
885 For the hourly application, the advantage of the LSTM model will become pronounced,  
886 as a larger number of past values would be required to capture the hysteretic flow re-  
887 cession dynamics.

888 It might be worth noting that our findings are based on an effort to find patterns  
889 in the “data-based” modeling result (i.e., the LSTM model results) and to explain these  
890 patterns. There are hydrologic models, such as the two bucket model operating in par-  
891 allel, that could reproduce these patterns. When the dynamics of the faster bucket be-  
892 come negligible to the discharge flowing out of the entire system (i.e., during the late time  
893 recession), the slower bucket dominates the flow dynamics, which would then determine  
894 the attractor. Depending on the relative contribution of each bucket, the early time re-  
895 cession dynamics can show event-to-event variability. While such a model has been ap-  
896 plied to explain the dynamics shown in the recession plot (e.g., Gao et al., 2017), the ex-  
897 istence of the attractor in the recession plot and its relation to the master recession curve  
898 has not been discussed. That is because such a model application is, in general, limited  
899 to explain already *known* patterns (e.g., the time-variability of the early time recession  
900 dynamics). In terms of finding new patterns out of noisy data, we believe that apply-  
901 ing a “data-based” model is preferable as it is relatively free from model structure er-  
902 ror compared to models in which their structure is determined *a priori*. Here, a poten-  
903 tial advantage of using a ML model over the traditional data-based model where trans-

904 fer functions or autoregressive models are used is how flexibly the non-linearity of the  
 905 model can be considered as we described in section 2.2.

906 While we focused on analyzing one catchment, we believe that the ML model de-  
 907 signed to capture the flow recession dynamics and the developed analysis tool can be gen-  
 908 eralized in several ways to improve our understanding of catchment scale flow dynam-  
 909 ics. This analysis can easily be extended to the continental scale or to the global scale  
 910 by analyzing many catchments. Analyzing more catchments will allow us to examine if  
 911 catchment attributes (e.g., area, aridity index, topographical, geological, and ecological  
 912 properties) can explain some patterns, such as the existence of the dense area (includ-  
 913 ing the attractor) and its slope, concavity, and extent.

914 Machine learning tools are powerful in that the model structure is flexible. Rather  
 915 than using only discharge  $Q$  as an input variable like the model developed in this study,  
 916 other variables can be used in the function  $H$  to examine if there is a better surrogate  
 917 variable for the function or depending on a purpose of analysis. For example, the past  
 918 trajectory of precipitation  $J$  can be used in the  $H$  function when the prediction of an  
 919 ungauged basin is of interest. Also, both  $J$  and  $Q$  (and also  $ET$ ) can be used to better  
 920 capture the flow recession dynamics and the rising limbs. For better forecasting, the model  
 921 can also be trained while continuously updating the modeled  $Q$  as the input. Further-  
 922 more, the model can also easily be modified to estimate  $Q$  instead of  $g$ . We showed that  
 923 the machine learning model result provides a convenient way to extract information out  
 924 of the noisy catchment scale signature, the recession plot. Following the discussion in  
 925 Beven (2020a), we hope the approach we applied in this study, making inferences from  
 926 what the machine learned and what it needed to learn, will be useful for understanding  
 927 more catchment scale dynamics when such inferences are well guided by scientific knowl-  
 928 edge.

## 929 **Appendix A Non-hysteretic active storage-discharge relationship and** 930 **one-to-one relationship in the recession plot**

931 Let us assume that there is an invertible, one-to-one relation  $p$  so that  $S_a = p(Q)$ .  
 932 We also assume that  $p$  is differentiable. The temporal fluctuation of the active storage  
 933 during flow recession periods can be estimated as:  $dS_a/dt = -Q$  if we assume negli-  
 934 gible water exchange between the active storage and other compartments such as the in-  
 935 active storage and negligible evapotranspiration loss from the active storage. (This ac-

936 tive storage is identical to the "dynamics" storage in (Staudinger et al., 2017).) The or-  
 937 dinary differential equation can then be rewritten as  $dS_a/dt = (dp(Q)/dQ)(dQ/dt) =$   
 938  $-Q$  and then  $-(dQ/dt)/Q = 1/p'(Q)$ , and the right hand side term is, by definition,  
 939 one-to-one relation.  $1/p'(Q)$  is indeed  $g(Q)$ .

## 940 Acknowledgments

941 We gratefully acknowledge the support of National Science Foundation grants EAR-  
 942 2120113 and GCR-2121155. We also acknowledge support from the Phileology Foun-  
 943 dation of Fort Worth Texas. Additional funding support was provided by the Office of  
 944 the Vice President of Research at the University of Arizona and by the Technology and  
 945 Research Initiative Fund (TRIF) Water, Environmental, and Energy Solutions (WEES)  
 946 initiative at the University of Arizona (Shared Equipment Enhancement Funds). The  
 947 CAMELS dataset is available from <https://ral.ucar.edu/solutions/products/camels> (Newman  
 948 et al., 2015).
