Abstract

Option prices contain forward looking information about stock price volatility and, potentially, the probability of default. We develop a risk-neutral density (RND) model consisting of a mixture of two lognormal densities augmented with a probability of bankruptcy. To test the model we calibrate it to daily stock and option prices of six financial institutions during the onset of the 2008 financial crisis. We find that the addition of the probability of bankruptcy term substantially improves the quality of the fit of the RND. The bankruptcy probability and the shape of the RND for the institutions are examined, particularly on major event dates. We show that acquiring banks have lower bankruptcy probabilities than the acquired banks and that the RNDs of financial institutions reflect market shocks, especially through the implied bankruptcy probabilities.

Keywords: Option prices, Bankruptcy probability, Risk-neutral density, Financial crisis

It is interesting to observe how markets react to sudden or extreme changes in the financial environment and whether predictions of a financial crisis or bankruptcies can be observed in contemporaneous market prices. In particular, we use options data to generate market expectations of the future risk-neutral densities of stock prices to investigate whether the effects of news announcements and economic events are reflected in the option prices of financial institutions involved in the 2008 financial crisis. To improve the risk-neutral density model we explicitly include a probability of bankruptcy (or default) into our model for the risk-neutral density (RND).

As options prices embed future predictions of stock price densities, it is possible that some information about the financial crisis could have been revealed sooner in the options markets, rather than in the equity markets. In particular, it might be possible to infer the probability of future bankruptcy from options data. Additionally, the inclusion of a specific probability of bankruptcy term in the RND may also be able to explain option prices better, especially during an economic crisis.

To test our model we analyze the major events in the 2008 financial crisis to see if options data has any predictive power. We focus upon the forced mergers between JP Morgan (JPM) and Bear Stearns (BSC) on 13 March 2008, between Bank of America (BAC) and Merrill Lynch (MER) on 15 September 2008, and the bankruptcy of Lehman Brothers (LEH) and the near failure of AIG on 15 September 2008.

We find that a RND that consists of a mixture of lognormals and a probability of bankruptcy term (MLNbk) is able to reproduce the observed option prices far more effectively than competing models. For example, for Lehman Brothers over the period from January to September 2008, the mean squared option pricing error is 0.001 for the MLNbk model, compared to 0.202 for the standard lognormal (LN) and 0.003 for a mixture of lognormals (MLN). The probability of bankruptcy term is also non-trivial throughout the period. For example, from January 2008 until October 2009, AIG's probability of bankruptcy averages 4.53% with significant variation, peaking at a value of around 50%.

From a day-to-day analysis of the individual banks we find direct support for the inclusion of a probability of bankruptcy term in our RNDs. As the acquired banks were relatively fragile,

we find that the acquired banks had a higher probability of bankruptcy. We also observe how even during extreme events like the financial crisis the risk-neutral densities provide a large amount of information about possible future events.

Our research is primarily about the forward-looking bankruptcy information provided by option prices. An alternative source for such information is provided by spreads for credit default swaps, so this paper includes some comparisons between the probabilities implied by option and CDS markets. The option methodology requires more price inputs, but has the advantage that it estimates the entire risk-neutral distribution of future prices.

We emphasise that all the probabilities obtained from option prices and CDS spreads are risk-neutral. In theory, either a change in perceptions of real-world probabilities or a change in the market's tolerance for risk changes is sufficient to explain a risk-neutral change.

In the default probabilities and bankruptcy estimation field, various kinds of historical data have been considered. Accounting variables, such as the ratios of working capital to total assets, retained earnings to total assets, earnings before interest and taxes to total assets, market equity to total liabilities, and sales to total assets, were used by Altman [1968]. Zmijewski [1984] considered the ratio of net income to total assets, the ratio of total liabilities to total assets, and the ratio of current assets to current liabilities. Also, balance sheet data and debt information are considered by Bharath and Shumway [2008] and Amel-Zadeh [2011]. Among others, Agarwal and Taffler [2008] and Fabozzi, Chen, Hu and Pan [2010] used stock prices. Shumway [1999] found that many accounting ratios are poor predictors, while market driven variables are strongly related to the probability of bankruptcy. He found that larger, less volatile firms, with high past returns had lower risk of bankruptcy. However, Agarwal and Taffler [2008] found that market-based models are not superior to accounting-ratio-based models.

The use of option prices to directly infer bankruptcy probabilities has been limited.¹ An exception is Camara, Popova and Simkins [2011] who assume RNDs are composed of a

¹ The Merton [1974] methodology provides bankruptcy information but relies on counterfactual assumptions about price dynamics. The restrictive assumptions of the model typically include: all liabilities mature on one

single lognormal density augmented with a probability of bankruptcy. To avoid the rigid shape of the lognormal density, we combine two lognormal densities augmented with a positive probability of bankruptcy (MLNbk). We find that this amendment causes the density shape to describe investors' expectations well. For example, for Lehman Brothers the lognormal model with bankruptcy (LNbk) matches options with a mean squared error which is over thirty times larger than the corresponding error for the MLNbk specification. Recently, Chen and Fong [2012] illustrate mixtures of lognormal densities for a few banks during the 2008 crisis, but do not consider a bankruptcy state. Birru and Figlewski [2012] discuss option-implied expectations for the U.S. equity sector during the fall of 2008, as revealed by RNDs for the S&P 500 index.

There are two advantages to using options data. First, options prices are forward-looking measures which reflect aggregate risk-neutral expectations for the underlying stock price until expiry of the derivative contracts. Second, these data have a high level of information efficiency. Option-implied volatilities and densities have strong forecasting ability, especially when the forecast horizon is either one month or three months (Poon and Granger [2003], Liu, Shackleton, Taylor and Xu [2007], Shackleton, Taylor and Yu [2010]).

In this paper, we estimate the daily RNDs of financial institutions during the financial crisis and observe how the RNDs react to major events. There are various methods to estimate risk-neutral densities. For example, the quadratic implied volatility method is a simple and efficient way to estimate a risk-neutral density. Malz [1997a, 1997b] proposed estimating the implied volatility curve as a quadratic function of the Black-Scholes options' delta and the method has been applied to equity markets by Bliss and Panigirtzoglou [2002], Liu, et al. [2007], and Taylor, Yadav and Zhang [2009]. A related methodology is explained in detail by Birru and Figlewski [2012].

Previous research has identified some advantages of a mixture of lognormal densities. Melick and Thomas [1997] extracted density function for crude oil futures from option prices and found that a mixture of lognormal distributions characterized market information better than a

known date, default triggered only at maturity, normally distributed asset returns (Hillegeist, Keating, Cram and Lundstedt [2004], Agarwal and Taffler [2008]).

single lognormal assumption. Jondeau and Rockinger [2000] compared the quality of risk-neutral densities estimated from various models. They found that a method based on a mixture of lognormal densities provides a better fit to options prices with short-term maturity than other methods based on either a Hermite approximation or a jump-diffusion process. Liu, et al. [2007] showed the mixture density provide a better fit than the Malz method. We follow this literature and consider a mixed lognormal density with possible bankruptcy in this paper.

The financial crisis period is a natural setting to test our model. First, we anticipate that the probability of bankruptcy will be non-trivial over this period and also the uncertainty of the period provides a robust test of competing RND models. As background, in 2007, an increase in subprime mortgage defaults triggered a liquidity crisis. The downgrading of mortgage-backed securities made the lending market even worse. In interbank funding markets, banks became unwilling to provide liquidity to other banks. The resultant liquidity dry-ups, market declines and defaults led to the financial crisis (Allen and Carletti [2008], Brunnermeier [2009]).

JP Morgan acquired Bear Stearns on 17 March 2008. Lehman Brothers declared bankruptcy on 15 September 2008. At about the same time, seeing the signs, Merrill Lynch announced that it had been sold to Bank of America. In related literature, the “forced merger” between JP Morgan and Bear Stearns was considered by Allen and Carletti [2008] and Rhee [2010]. The US government feared that the bankruptcy of Bear Stearns would cascade through the financial system and lead to a string of bankruptcies. The government forced relatively sound banks to merge with risky banks in order to stabilize the financial crisis and protect the public interest.

There has been fruitful research into bank mergers. Previous research on mergers has focused on changes in market values, costs and revenues, and managerial efficiency (Focarelli, Panetta and Salleo [2002], Amel, Barnes, Panetta and Salleo [2004]). It is worth paying attention to how forced mergers affect the risks of the institutions involved. Generally, however, in the fields of default forecasting or bankruptcy forecasting, financial institutions

are excluded (Shumway [2001], Agarwal and Taffler [2008], Bharath and Shumway [2008]).² Unlike previous research, we compare the daily probability of bankruptcy for financial institutions during the financial crisis, especially before and after the announcement of forced mergers. In this paper, both the forced merger between JP Morgan and Bear Stearns and that between Bank of America and Merrill Lynch are considered. It is interesting to check whether the acquiring banks have lower implied bankruptcy probabilities than the acquired banks. Also, the paper includes the American International Group (AIG) and Lehman Brothers cases. We anticipate finding that the probability of bankruptcy increases when a bank is strongly expected not to survive, e.g. to be acquired or announce bankruptcy in the near future.

Overall, our new model shows ex-ante bankruptcy chances and the shape of the risk-neutral density. This can provide valuable information for risk management, investment decisions, and policy decisions. It is expected to reveal that a large density in the left tail reflects market uncertainty about crisis firms and also a useful measure of bankruptcy risk or default.

HISTORICAL TIMELINE

On March 11, 2008, the Federal Reserve announced a \$200 billion Term Securities Lending Facility. As Bear Stearns was a small high-leveraged bank with large mortgage exposure this led to concerns about its future. On March 12, the late acceptance of an interest rate swap from Goldman Sachs was interpreted as a sign that Bear Stearns was in trouble, causing nervousness among its hedge fund clients. Bear Stearn's liquidity dried up dramatically the next day.

On March 14, the Federal Reserve Bank agreed to provide a \$25 billion loan to Bear Stearns to provide liquidity for up to 28 days. To prevent instability in the credit default swap market, the government intervened in the merger between JP Morgan and Bear Stearns. On March 17, JP Morgan offered to acquire Bear Stearns at a price of \$2 per share, dramatically different

² These authors consider accounting-ratio data. Because the accounting rules, asset valuations and other characteristics of financial institutions are different from others, they exclude these institutions from their samples.

from the shares' traded price of around \$80 one week earlier. On March 24, the offer was raised to \$10 per share to pacify angry shareholders. JP Morgan completed its acquisition of Bear Stearns on May 30, 2008 (Brunnermeier [2009]).

From March, 2008 onwards, Lehman Brothers was reliant on overnight funding from the Federal Reserve. On August 20, shares in Lehman Brothers had fallen by almost 66% from March prices and they held secret talks to discuss selling a major proportion of its shares to the Korea Development Bank. On September 9, as it became clear the deal would fail, Lehman's shares plunged. The Federal Reserve Bank held a meeting with all the major banks' representatives to save Lehman Brothers. However, on September 14 Bank of America abstained from bidding for Lehman Brothers without the government's financial help. The next morning, Lehman Brothers announced bankruptcy. Fearing for the future, Merrill Lynch rushed into an agreement to be acquired by Bank of America. The offer by Bank of America was 70% higher than Merrill's shares at the close on 12 September.

AIG, the biggest commercial insurance provider in the US, had been active in the derivatives business, including credit default swaps which insure against corporate default. On August 7 2008, AIG announced a higher than expected loss for large subprime write-downs. On September 15, AIG's shares fell 93%. On September 17, to prevent the collapse of the giant insurer the Federal Reserve announced that it would lend AIG emergency funds in return for an 80% controlling stake. On November 9, AIG was granted a \$150 billion government bailout plan (Brunnermeier [2009]). As AIG played such an important role in the US financial market, the US government provided bailouts to save it and to stabilize the financial market. In the end, it survived the financial crisis. The major events of these institutions are summarized in Table I.

DATA

Market expectations are inferred from option prices and CDS spreads for six financial institutions during 2008 and 2009, with results also presented for Bear Stearns during the second half of 2007. The inclusive dates for the six sample periods are provided in Table II.

Volatility expectations implied by the option prices are compared with daily realized volatilities calculated from two-minute returns, obtained from prices in the TAQ database. The realized variance for day t is the sum of squares of two-minute returns:

$$\hat{\sigma}_t^2 = \sum_{i=1}^m r_{t,i}^2$$

from which the annualized realized volatility for day t is calculated as $\sqrt{252}\hat{\sigma}_t$.

Option prices

Daily end-of-day settlement options prices are obtained from OptionMetrics. The option contracts are American. We concentrate our analysis on short-term, out-of-the-money (OTM) option contracts for which the early exercise premia can be ignored. Call and put prices for contracts with the same strike and expiry contain the same information, so that ignoring in-the-money (ITM) prices does not lose information when matching calls and puts are traded. A second advantage of OTM options is that they are more actively traded than ITM options.

To simplify equations and calculations, the option contracts are assumed to be European and written on synthetic futures contracts, with futures and options always having matching expiry times. As is well-known, the synthetic futures price F depends on the spot price S , the risk-free rate r and the present value of dividends during the time T until the futures contract expires:

$$F = e^{rT} [S - \text{PV}(\text{dividends})]. \quad (1)$$

The term r is calculated by Ivy DB from a term structure of zero-coupon interest rates, which is derived from Libor rates and Eurodollar futures prices. The dividends are extracted from OptionMetrics.

Option prices for five strike prices and a common expiry date are required to estimate the most general specification of the risk-neutral density considered in this paper. For any day and firm, whenever option prices for calls and puts are available for five OTM strikes we use all of the OTM option prices; for a strike X , calls are defined to be OTM when $X > F$ and puts are OTM when $X < F$. The second nearest-to-maturity options are chosen whenever

they provide five or more OTM option prices. Table III reports that this is possible for between 67% (BAC) and 86% (LEH) of the days in our sample.

When there are less than five available strikes for the second nearest contracts, we switch to the third nearest-to-maturity contracts if possible. When there are also less than five available strike prices for these contracts, we delete the sample day. In a few cases, there are sufficient strikes for the second or third nearest contracts but the sum of squared pricing errors, described in the next Section, is very high and more than ten times the standard deviation for the firm; we then use the nearest time-to-maturity, providing it has five available strikes and, furthermore, there are no dividend payments before the nearest expiry date. Table III shows that the nearest options are used for less than 5% of sample days, while the frequency for the third-nearest options varies from 12% (LEH) to 31% (BAC).

There are a small number of cases when we can only obtain five or more available strikes by including ITM puts. This has been done for 16 days for AIG, four days for BAC, and one day each for BSC and MER. These cases occur when the spot price is low and there is either zero or one available OTM put.

We have a satisfactory number of strikes for all days in our sample periods for JPM, LEH and MER. Table III reports that 3% of the days are discarded for BAC, 15% for BSC and 26% for AIG.

CDS spreads

Daily spreads for credit default swaps on senior debt are obtained from Bloomberg and Datastream. We choose a contract maturity of one year, rather than five years, because we are interested in default expectations over the shortest periods that can be revealed by market prices. The risk-neutral, implied probabilities of default are calculated using the method of Bharath and Shumway [2008]. Implementation of their method requires the market expectation of the recovery rate after any default. Sarbu, Schmitt and Uhrig-Homburg [2013] estimate an average implied recovery rate of 50% for the senior debt of financial companies, which is very similar to the average recovery rate for the banking sector in Jankowitsch, Nagler and Subrahmanyam [2014]. Consequently, we assume a recovery rate of 50%.

METHODOLOGY

Distributions

Many methods can be used to estimate risk-neutral densities from option prices, including several reviewed in Taylor [2005] and Figlewski [2009]. One of the most popular density specifications is a mixture of two lognormal densities, first proposed by Ritchey [1990] and applied in numerous studies including Melick and Thomas [1997], Brigo and Mercurio [2002] and Liu et al. [2007]. The mixture of lognormals (MLN) density has three more parameters than the lognormal (LN) density, which permits a variety of flexible shapes for the risk-neutral density (RND). In particular, fitted MLN densities possess appropriate negative levels of skewness and positive excess kurtosis³. The MLN density also offers the possibility of interpreting the RND as the density of a process having two possible futures states, which might be associated firstly with bad news and secondly with good news.

The MLN density for time T assumes the underlying asset price will always be positive when options expire T years after the present time. We generalise the distribution of the future spot price to allow for bankruptcy, which is here identified with the extreme state $S_T = 0$. We allocate weights π_1 and π_2 to two lognormal distributions and the remaining weight, $1 - \pi_1 - \pi_2$, to the probability of bankruptcy.⁴

Our most general risk-neutral, cumulative distribution function (c.d.f.) for S_T , at time zero, is

³ All fitted RNDs estimate the tails of the density by extrapolating outside the range of observed strike prices. The MLN tails are thinner than provided by alternative density models, such as the generalized extreme value tails assumed in Figlewski [2009] and Birru and Figlewski [2012].

⁴ Incorporating a positive chance of bankruptcy into the RND is an extreme way to fatten the left tail. There may be credible alternative ways to do this, but they are beyond the scope of our current research.

$$G(x|\theta) = \Pr(S_T \leq x) = 1 - \pi_1 - \pi_2 + \pi_1 G_{LN}(x|F_1, \sigma_1) + \pi_2 G_{LN}(x|F_2, \sigma_2). \quad (2)$$

This c.d.f. is defined by parameters $\theta = (\pi_1, \pi_2, F_1, F_2, \sigma_1, \sigma_2)$ and two lognormal c.d.f.s $G_{LN}(\cdot)$. The component lognormal distributions have expectations F_1 and F_2 , and their cumulative functions are given by

$$G_{LN}(x|F_i, \sigma_i) = \Phi\left(\frac{\log(x) - [\log(F_i) - 0.5\sigma_i^2 T]}{\sigma_i \sqrt{T}}\right), \quad i = 1, 2 \quad (3)$$

with $\Phi(\cdot)$ the c.d.f. of the standard normal distribution. The risk-neutral, density function of S_T is defined for positive prices x by a linear function of lognormal densities:

$$g_Q(x|\theta) = \pi_1 g_{LN}(x|F_1, \sigma_1) + \pi_2 g_{LN}(x|F_2, \sigma_2) \quad (3)$$

with

$$g_{LN}(x|F_i, \sigma_i) = \frac{1}{x\sigma_i\sqrt{T}} \phi\left(\frac{\log(x) - [\log(F_i) - 0.5\sigma_i^2 T]}{\sigma_i \sqrt{T}}\right) \quad (4)$$

and with $\phi(\cdot)$ the density of the standard normal distribution.

For the risk-neutral measure Q , we always have $E^Q[S_T] = F$ with F representing the time-zero, futures price defined by (1). Consequently, $\pi_1 F_1 + \pi_2 F_2 = F$. Additional constraints on the vector θ are $\pi_1, \pi_2 \geq 0$, $\pi_1 + \pi_2 \leq 1$ and $F_1, F_2, \sigma_1, \sigma_2 > 0$. All risk-neutral moments of the distribution of S_T can be obtained from

$$E^Q[S_T^n|\theta] = \sum_{i=1}^2 \pi_i F_i^n \exp(0.5[n^2 - n]\sigma_i^2 T). \quad (6)$$

As the general distribution defined by (2) combines MLN and bankruptcy features we refer to (2) by using the acronym MLNbk. The MLNbk distribution has six parameters restricted by one equality constraint, so there are five free parameters. We claim later that MLNbk describes our option prices better than the following three special cases: (1) the lognormal (LN) distribution occurs when $\pi_1 = 1$ and $\pi_2 = 0$ and it has one free parameter (i.e. σ_1), (2) the lognormal with bankruptcy (LNbk) distribution of Camara, Popova and Simkins [2011] is given by $\pi_1 \leq 1$ and $\pi_2 = 0$ and has two free parameters (π_1, σ_1) , (3) the MLN distribution

excludes bankruptcy by requiring $\pi_1 + \pi_2 = 1$ and thus has four free parameters $(\pi_1, F_1, \sigma_1, \sigma_2)$. Note that LNbK can be obtained as the special limiting case of MLN when $F_2 \rightarrow 0$ and σ_2 is any fixed positive number. Consequently, we can state $LN \subseteq \text{LNbK} \subseteq \text{MLN} \subseteq \text{MLNbK}$.

Option pricing

European option prices are discounted, risk-neutral expectations of the option payoffs at expiry. The Black [1976] pricing formula for European options on futures is simply an application of risk-neutral pricing for a lognormal distribution, for which we represent call and put prices respectively by the notation $c_B(X, F, \sigma, T)$ and $p_B(X, F, \sigma, T)$; here X is the strike price, F is the time-zero futures price and σ is the annualized volatility. Therefore, when the underlying asset price on the expiry date has a MLNbK distribution, at time 0 the theoretical price of a call option is given by:

$$c(X|\theta) = \pi_1 c_B(X, F_1, \sigma_1, T) + \pi_2 c_B(X, F_2, \sigma_2, T), \quad (7)$$

as call options are worthless if the firm is bankrupt. Put options are worth X if the firm is bankrupt, so their theoretical prices for the MLNbK distribution are:

$$p(X|\theta) = e^{-rT}(1 - \pi_1 - \pi_2)X + \pi_1 p_B(X, F_1, \sigma_1, T) + \pi_2 p_B(X, F_2, \sigma_2, T). \quad (8)$$

These option prices depend on the time-zero futures price F through the risk-neutral constraint, as $F_2 = (F - \pi_1 F_1) / \pi_2$ when $\pi_2 \neq 0$.

Parameter estimation

All parameters are estimated by minimizing the average of the squared differences between traded prices for OTM options and the corresponding theoretical OTM prices. For a set of traded strikes X_1, \dots, X_N , and OTM prices $O_{OTM}(X_i)$, we minimize

$$H(\theta) = \frac{1}{N} \sum_{i=1}^N [O_{OTM}(X_i) - O(X_i|\theta)]^2, \quad (9)$$

with $O(X_i|\theta) = c(X_i|\theta)$ when $X_i > F$ and $O(X_i|\theta) = p(X_i|\theta)$ when $X_i < F$.

A summary of the parameter estimates obtained from the option prices included in our study is provided by Tables III and IV. Table III summarises the values of H across the sample periods. As the distributions of the H -values are positively skewed, we state results for both means and medians. The LNbk distribution has two states (survive, with a lognormal distribution, or go bankrupt) and it fits the option prices more accurately than a single lognormal distribution. The median H for LNbk divided by the median H for LN varies from 11% to 27% across institutions; the ratio of means varies from 16% to 34%. However, the LNbk distribution is simply a limiting case of the MLN distribution, which allows for two general states. When we compare H -values for LNbk and MLN we find the more general distribution has median values which are between 6% and 10% of the median values for the special case; the ratios are 8% to 12% for mean values. The MLNbk distribution is our most general specification and its values of H are a notable improvement upon all special cases. The MLNbk distribution has medians which are between 19% and 37% of the MLN medians, with mean ratios from 24% to 55%.

Table IV shows the means and standard deviations of the estimated parameters for the MLNbk distribution. As is typical in the MLN literature for equity markets, the lower-expectation state is less likely but more volatile, i.e. when $F_1 < F_2$ then $\pi_1 < \pi_2$ and $\sigma_1 > \sigma_2$. The third state for MLNbk is seen to have a low average probability of bankruptcy across each sample period, with $1 - \pi_1 - \pi_2$ varying from 1.2% for BSC to 4.5% for AIG.

EMPIRICAL RESULTS

We first use option prices to compare the risk-neutral probability of bankruptcy for the six financial institutions, contrasting the chances for acquiring, acquired, bankrupt and bailed-out institutions. It is important to remember that all the probabilities are risk-neutral; they will change if either real-world probabilities change or the market's tolerance for risk changes. Next, we compare the probabilities extracted from option prices with those implied by CDS spreads. We find that similar information is revealed by the two sources. Finally, we provide separate case studies for each institution, and discuss changes in risk-neutral bankruptcy perceptions and densities especially when major relevant news items are announced.

Comparison of the probability of bankruptcy across institutions

Figure 1 shows the bankruptcy probability for the two acquiring banks, JP Morgan and Bank of America. The probability was less than 2% before September 2008⁵. The probability of bankruptcy around the Bear Stearns crisis in March 2008 was generally smaller than around the Lehman Brothers failure in September 2008. The probabilities were relatively high from September 2008 to June 2009, while in the second half of 2009 they decreased to less than 1%.

The probability of bankruptcy for the acquired banks, Bear Stearns and Merrill Lynch, is shown in Figure 2. The respective probabilities on the acquisition dates are 27% (BSC, March 17) and 11% (MER, September 15); these are end-of-day probabilities, calculated after the announcements. The average probability of bankruptcy for the acquiring banks, calculated *across the month prior to acquisition*, is compared with that of the acquired banks in Table V. The acquiring institutions have lower averages, of 0.7% (JPM) and 0.9% (BAC), than those of the acquired institutions, which are 3.1% (BSC) and 2.3% (MER). These results are consistent with the market implying a higher chance of failure for the acquired institutions, reflecting beliefs that they are more fragile than the relatively sound acquirers. These results also provide support for the MLNbk model.

Figure 2 also shows that the only bankrupt institution in our sample, Lehman Brothers, had the highest implied probabilities, which went as high as 54% on September 15, 2008; again this is a post-announcement probability. Figure 2 also shows that American International Group had high probabilities for several months after the Lehman bankruptcy.

Comparisons of probabilities of bankruptcy implied by option contracts and credit default swaps

Option prices provide implied risk-neutral probabilities of bankruptcy over relatively short time horizons defined by times to expiry, while one-year CDS prices provide probabilities

⁵They refer to varying time horizons, which are usually between 25 and 45 trading days.

over a one-year horizon. The two markets thus provide implied probabilities for different horizons, in the same way that two-month and one-year interest rates and implied volatilities provide two observations from the respective term structures.

Table V shows the probability of bankruptcy averages during one-month periods preceding the key dates in March 2008 (for JP Morgan and Bear Stearns), and September 2008 (for the other four institutions). We observe that the six probabilities rank in the same order for both the options and CDS sources, so their rank correlation is one. This shows that the two sources agreed about the relative bankruptcy risks. As the average option lifetimes are just under two months it is not surprising that the option implied probabilities are smaller than the one-year CDS probabilities. Table V also shows the equivalent CDS probabilities over option lifetimes, after assuming a constant intensity for default for the next year. The option implied probabilities are then seen to be larger than the CDS probabilities, by factors varying from 1.7 to 3.4. The higher option probabilities are consistent with a declining term structure of bankruptcy risk; during a crisis we expect a higher chance of bankruptcy during the next two months than during subsequent two-month periods.

A second comparison of option and CDS information can be attempted by asking if one source leads the other in providing relevant information. Some evidence about relative timing is given by finding the correlation between the bankruptcy chance on day t from options data and the chance on day $t + \tau$ from CDS prices, denoted by r_τ . We find $r_1 > r_0 > r_{-1}$ for three institutions (JPM, BAC, AIG), while $r_1 < r_0 < r_{-1}$ for two (BSC, MER) and $r_0 > r_1 > r_{-1}$ for one (LEH). We consider the evidence from these correlations to be inconclusive.

Some visual comparisons are shown on Figures 3 and 6a, which confirm that the options and CDS probabilities provide complementary information.

We now consider the option implied probabilities of bankruptcy for the financial institutions in detail, commencing with the two which were central to the March 2008 crisis, namely Bear Stearns and JP Morgan.

Bear Stearns (BSC)

Figure 3 shows that BSC had a bankruptcy chance below 2% before Monday March 10. As liquidity dried up, the probability increased reflecting rising fear among investors. On Monday March 17, JP Morgan offered to acquire Bear Stearns at a low price when the implied probability of bankruptcy was 27%. Figure 4 shows four examples of market expectations, as revealed by the estimated MLN and MLNbk risk-neutral densities, on March 11, March 14, March 17 and April 1. The major events involving Bear Stearns during this period are as follows.

On Tuesday March 11, the Federal Reserve announced a \$200 billion Term Securities Lending Facility. Some investors might have read this as a sign that Bear Stearns might be in difficulty, because it was a small high-leveraged bank with a large mortgage exposure. The bankruptcy estimate rose to 3% which reflected the increasing bankruptcy risk. As can be seen from Figure 4, the means of the two lognormal components in the MLNbk density are \$47 and \$70. This could be interpreted as different market expectations about whether Bear Stearns was in difficulty. It is also seen that one lognormal component in the MLN density has a mean below \$10. This information is partially reflected by the bankruptcy risk in the MLNbk distribution, which illustrates the key difference between the MLN and MLNbk distributions. The average pricing errors are 0.0170 and 0.0044, and the MLNbk distribution more accurately describes the expectations of investors over the options life until April 19.

On Wednesday March 12, the late acceptance of an interest rate swap contract from Goldman Sachs was interpreted as a rejection and a sign that BSC might be in trouble. This misunderstanding was leaked to the media, causing nervousness among Bear Stearns' hedge fund clients. The Bear's liquidity dried up dramatically the next day. The probability of going bankrupt was again 3% and it increased on Thursday March 13 to 5%.

On Friday March 14, JP Morgan and the Federal Reserve Bank agreed to provide a secured loan for up to 28 days to allow Bear Stearns to access liquidity and alleviate the need for a 'fire sale' of mortgage-backed securities.⁶ The bankruptcy chance climbed to 11% and the

⁶ From <http://www.ft.com/cms/s/0/2814f4d0-f1fb-11dc-9b45-0000779fd2ac.html> and <http://www.ft.com/cms/s/0/43697fa6-f1cb-11dc-9b45-0000779fd2ac.html>.

annualized realized volatility⁷ soared to 634%, reflecting the serious liquidity problem at BSC.

The credit default swaps market could have become unstable without a rescue plan.⁸ To save the financial system from collapse, over the weekend of March 15 and 16 the Federal Reserve Bank of New York helped to arrange a deal between JP Morgan and Bear Stearns. This emphasises that Bear Stearns was fragile and at high risk of bankruptcy.

On Monday March 17, JP Morgan offered to acquire Bear Stearns at only \$2 per share, far below its share price of \$30 on March 14. The bankruptcy chance increased substantially again, to 27%, while realized volatility was again very high at 453%. The low price offer highlights the risks carried by investors during the credit crunch.⁹

A week later, on Monday March 24, the offer to acquire was raised to \$10 per share to pacify angry shareholders. On April 1, the Federal Reserve cleared the way for JP Morgan to buy Bear Stearns' bank holdings. The bankruptcy rate decreased to 0.6% and Figure 4 shows the left tail of the risk-neutral density is now thinner, with far less chance of a very low future price. JP Morgan completed its acquisition of Bear Stearns on May 30, 2008 (Brunnermeier [2009]).

JP Morgan (JPM)

The market implied estimates of future bankruptcy are generally lower for JP Morgan than the other five institutions. Figures 1 to 3 show JPM is the only institution whose maximum bankruptcy probability is below 10%. The probability is below 2% until the crisis events of September 2008 and then increases, with most values between 2% and 4% until March 2009 and then the values fall below 1%. Note that of the six banks that we study in detail, JPM also has a significantly lower realized volatility, also consistent with a lower probability of bankruptcy. The maximum realized volatility for JPM is 227%, notably below the next

⁷ Except for LEH, figures showing realized volatilities are omitted to conserve space. Realized volatilities are almost always below 100% before the crisis events.

⁸ From <http://www.time.com/time/business/article/0,8599,1723152,00.html>.

⁹ From <http://www.ft.com/cms/s/0/e2206ed2-f380-11dc-b6bc-0000779fd2ac.html>.

highest which is 384% for MER. The average realized volatility for JPM is 55%, while over a similar period including September, 2008, the next lowest is 67% for BAC¹⁰.

As already discussed, Bear Stearns was acquired by the relatively stable JPM in March 2008. The estimated bankruptcy risk for JPM increased, temporarily, on March 17 to 2%. However, Figure 5 shows that on this day the risk-neutral distribution has low probabilities for future low prices. From Figure 5, the densities for four later days, discussed below, also confirm that JPM was perceived to be “relatively strong” between August 2008 and June 2009.

On August 12, JPM reported a \$1.5 billion write-down in July. JPM said that trading conditions in the mortgage market had seriously deteriorated in July due to cut-price sales of mortgage-backed securities; Fannie Mae and Freddie Mac had been less willing to support the market.¹¹ The bankruptcy chance for JPM was then 0.8% and the risk-neutral density has a relatively fat left tail. This may reflect the credit conditions faced by JPM.

On September 15, JPM was one of ten large banks which agreed to contribute together to provide a \$70 billion liquidity fund to mitigate the expected failure of Lehman Brothers.¹² The bankruptcy chance for JPM moved up to 1.8%, which may reflect systemic credit risk as it was a relatively large and stable institution.

On September 26, JP Morgan acquired Washington Mutual’s bank deposits, assets and its troubled mortgage portfolio from the Federal government and became the largest US depository institution.¹³ Because some of the transferred deposits were uninsured, investors had different viewpoints about the benefit of the acquisition to JPM. The bankruptcy chance of 1.5% and the long left tail in the risk-neutral density shows uncertainty about the medium-term prospects of JPM.

¹⁰ BSC average realized volatility is 56% but this only covers the period until May, 2008.

¹¹ From <http://www.ft.com/cms/s/0/5b3f0ea2-67fa-11dd-8d3b-0000779fd18c.html>.

¹² From http://www.ft.com/cms/s/0/136a27d8-82d0-11dd-a019-000077b07658.dwp_uuid=11f94e6e-7e94-11dd-b1af-000077b07658.html.

¹³ From <http://www.ft.com/cms/s/0/f652afe0-8bf2-11dd-8a4c-0000779fd18c.html>.

On May 7, 2009, a stress test by the government showed that JPM was adequately capitalized and was more able to repay bailout dollars than its peers.¹⁴ The announcement of the test result should have reassured investors and the bankruptcy chance fell to 0.6%. The pronounced left tail, seen in previous risk-neutral densities, disappears and the density becomes almost symmetric. This indicates that the market had few concerns about JP Morgan surviving the liquidity crisis.

Lehman Brothers (LEH)

Panel A of Figure 6 shows that the options market implied that Lehman Brothers was unsafe from mid-March 2008 until it went bankrupt six months later. Before the Bear Stearns crisis the bankruptcy risk was less than 1%, but it peaked at 9% on March 17 when Bear Stearns was rescued. Subsequently, the estimated risk fell for two months before rising again, reaching 19% on 11 September and then 54% on September 15 when LEH announced bankruptcy.

Panel B of Figure 6 shows three measures of annualised volatility which all soar around March 17 and September 15; these measures are the realised volatility (RV), the conditional standard deviation from the GJR-ARCH model calculated from daily returns and the standard deviation of the MLN risk-neutral density.

We now discuss some of the major events for Lehman Brothers in 2008. On January 17, having already lost 2,500 jobs, LEH announced plans to cut a further 1,300 jobs in its domestic mortgage division. At this time LEH did not have known liquidity issues, the estimated bankruptcy chance was less than 1% and the estimated risk-neutral densities, shown in Figure 7, do not reveal any market concerns. During March, however, LEH relied on overnight Fed funding to survive during the Bear Stearns crisis period. The bankruptcy rate reached 9% on March 17, when Figure 7 shows bimodal densities for the stock price one month later. One mode is at a few dollars while the other mode is above \$40, so the information provided by the densities is evidence of major concern that LEH may collapse.

¹⁴ From http://www.nytimes.com/2009/05/08/business/08bank.html?_r=1&scp=2&sq=stress%20test%20results%20may%207&st=cse and <http://www.reuters.com/article/americasRegulatoryNews/idUSN1154040620090511>.

On August 20, Lehman Brothers held secret talks to sell the majority of its shares to the Korea Development Bank. On Tuesday September 9, as it became clear the deal would fail, the LEH share price plunged. The estimated bankruptcy chance shot up to 18%, reflecting the negative news. On Thursday September 11, Lehman Brothers announced plans to contract as a way to survive the credit crisis. This news came after LEH reported its worst ever loss of \$3.9 billion for the third quarter, spurred by \$7.8 billion in credit-related write-downs.¹⁵ The bankruptcy risk remained at a high level, 19%, and Figure 7 now shows very low share price expectations.

In an effort to save LEH, the Federal Reserve Bank held meetings with representatives of all the major banks. On Sunday September 14, Bank of America, lacking a government guarantee, withdrew from bidding for Lehman Brothers. The next morning, on Monday September 15, Lehman Brothers announced bankruptcy. For this day, and following the announcement, the realized volatility and bankruptcy chance rose to extremely high levels, respectively 1,058% and 54%.

Merrill Lynch (MER)

Comparing Figure 8 for Merrill Lynch with Figure 6 for Lehman Brothers shows similar expectations during the March 2008 crisis but important differences during the deeper crisis in September 2008. Both institutions experienced perceptions of weakness on March 17 and a bankruptcy estimate of 9%. MER, in contrast to LEH, does not have estimates above 10% before the weekend of September 13-14 when MER was able to arrange a sale to Bank of America.

Before the Bear Stearns crisis, the MEL bankruptcy chance was less than 1%. This occurred despite the announcement on January 17 of a net loss of \$7.8 billion, which included a \$14.1 billion write-down on investments related to sub-prime mortgages.¹⁶ The risk of bankruptcy then remained at a low level, 0.3%.

¹⁵ From <http://www.ft.com/cms/s/0/c4cb3b92-7f98-11dd-a3da-000077b07658.html>.

¹⁶ From <http://news.bbc.co.uk/2/hi/business/7193915.stm>.

Later, on July 28, Merrill Lynch announced a \$8.5 billion share offer and a \$5.7 billion fire sale of toxic mortgage securities.¹⁷ The share return on this day was -12% and the probability of bankruptcy increased to 2.3%.

On Sunday September 14, as its competitor Lehman Brothers was sinking, Merrill Lynch “reading the signs ... announced ... that it had sold itself to Bank of America for \$50 billion” (Brunnermeier [2009]). This price was equivalent to \$29 per share, which was 70% higher than Merrill’s most recent traded stock price. The realized volatility and bankruptcy chance on Monday September 15 were 172% and 11% respectively. The relatively high probability of future bankruptcy on this and subsequent days may reflect a lack of confidence either in the sale of MEL or in the strength of its rescuer. Figure 9 shows the estimated risk-neutral densities on September 15 are highly skewed to the left, with expectations far below \$29.

Bank of America (BAC)

As shown by Figures 1 and 8, the market considered Bank of America to be relatively safe during the crises of March and September 2008, but less safe after these crises. The estimated probability of bankruptcy is 2% on September 15 and it is lower before then. There are several estimates around 5% later in 2008. These are followed by some estimates above 10% during the first half of 2009 and by much lower values later in the year. The five examples of BAC risk-neutral densities on Figure 10 show expectations falling as time progresses, because the share price falls, but they do not show high chances of very low prices in the future.

On Saturday September 13, Bank of America was seen as the leading contender to buy Lehman Brothers, but the US government was reluctant to provide public backing for a take-over.¹⁸ On Sunday September 14, Bank of America instead agreed to acquire Merrill Lynch.¹⁹ The inferred probability of bankruptcy for BAC on Monday September 15 increased, but only to 2.1%, which reflects some level of systemic credit risk following the LEH bankruptcy.

¹⁷ From <http://www.ft.com/cms/s/0/3bf7930e-5cf4-11dd-8d38-000077b07658.html>.

¹⁸ From <http://www.ft.com/cms/s/0/306f879c-812c-11dd-82dd-000077b07658.html>.

¹⁹ From http://www.ft.com/cms/s/0/0ba5fbd8-82a0-11dd-a019-000077b07658,dwp_uuid=11f94e6e-7e94-11dd-b1af-000077b07658.html.

On October 7, Bank of America reported its third quarter earnings which were less than analysts' expectations. BAC said it would raise \$10 billion of capital and cut its dividend in order to get through the credit crisis.²⁰ The immediate response to the negative news was a one-day return of -30%.

On October 14, the US government injected \$250 billion into the US banking system. As part of their plan, BAC was to get \$25 billion in government funds. In return, the government would take an equity position in the bank.²¹ While the one-day return was 15%, the probability of bankruptcy went to 3.3%. Thus market concerns about another bankruptcy were not eliminated by the injection announcement.

On Saturday December 20, S&P downgraded the ratings of six major US banks reflecting anxieties that financial crisis could be longer and deeper than previously expected. Bank of America's acquisition of Merrill Lynch raised concerns, because MEL could generate more write-downs in commercial real estate and leveraged loans.²² On Monday December 22, the bankruptcy estimate was 1.9%.

On January 15, 2009, BAC received a \$138 billion bailout. The bailout was to be used to improve the balance sheet at the newly acquired MEL and to guarantee potential losses on 'toxic assets'.²³ The BAC share price fell 20% on the day and the estimated probability of bankruptcy climbed to a new high level, of 12%. This clearly shows that market concerns were not alleviated by the bailout announcement.

By May the bankruptcy estimates were falling. Nevertheless, on May 7, stress test results exposed Bank of America's lack of capital to survive worst-case scenarios. The bankruptcy estimate was then 2.3%, compared with 0.6% for JP Morgan which was reported to be adequately capitalized. On May 20, BAC sold shares to raise \$13.5 billion, which represented considerable progress towards meeting its capital-raising requirement. On June 3, US banks

²³ From <http://www.ft.com/cms/s/0/7ebeb6b0-e35c-11dd-a5cf-0000779fd2ac.html>.

sold common shares and non-guaranteed debt to raise more money than required by regulators. Mutual funds and other large institutional investors bought shares aggressively and stock prices reflected the improving situation. BAC shares went up by 263% from March's low point, while JPM was up 118%.²⁴ With the improvement in liquidity conditions, the realized volatility and bankruptcy estimate decreased to 40% and 0.4%, respectively. The market gradually reverted to more normal conditions and the bankruptcy estimate was close to zero after August 2009.

American International Group (AIG)

As can be seen from Figures 1 and 2, AIG is the only financial institution in our sample to have several bankruptcy estimates above 20%, all of which occurred during 2008 after September 11. AIG was active in the derivatives business, including credit default swaps, which insure against corporate default. It was severely affected by the liquidity dry-up during the financial crisis. AIG received government bailouts between September 2008 and March 2009 and consequently survived the financial crisis. Afterwards its implied probability of bankruptcy stayed low, and close to zero after August 2009.

The estimated chance of bankruptcy is less than 3% in the first half of 2008, and increases after July 2008. On 7 August 2008, AIG announced a higher than expected loss for large subprime write-downs. The bankruptcy chance was then less than 1.5%. The slightly fat left tails of the risk-neutral densities in Figure 11 reflect concerns that AIG might perform worse in the near future.

On Friday September 12, S&P put AIG on a negative credit watch, signaling a possible rating cut. The bankruptcy chance and realized volatility were 13.5% and 23.8%. On Monday September 15, AIG made a deal with the New York insurance regulators to add liquidity. Despite the deal, all the major rating agencies downgraded AIG's long-term credit rating to reflect its losses from mortgage-related investments and credit derivatives.²⁵ Its share price reflected the shock of the credit downgrades and the dramatic news about LEH and MER.

²⁴ From <http://online.wsj.com/article/SB124398503075879165.html>.

²⁵ From http://www.ft.com/cms/s/0/abaf3dee-834d-11dd-907e-000077b07658,dwp_uuid=11f94e6e-7e94-11dd-b1af-000077b07658.html

The daily return (change in the price logarithm) from Friday's close to Monday's close was -93%. Panic is also shown by the very high realized volatility of 828%, and the bankruptcy risk estimate of 12%. The high volatility can be seen in Figure 11 which shows the fat tails of the risk neutral densities on September 12 and 15.

On September 16, the Federal Reserve announced that it would lend AIG \$85 billion in emergency funds in return for an 80% controlling stake. The implementation of a government stake was to prevent existing shareholders from taking advantage of a bailout.²⁶ The exceptionally high realized volatility of 1,237% and the bankruptcy risk of 11% indicate heightened fear about future uncertainty.

On September 18, the world's major central banks announced an injection of \$180 billion to improve liquidity. This action led to a decrease in overnight interbank lending. But the continuing increase in longer-term interbank lending rates indicated that liquidity among banks remained suspect.²⁷ The AIG return was 27%, and the realized volatility estimate decreased to 236%. This decrease reflects the positive features of the central bank actions, although strong concerns remain as the probability of bankruptcy increased to 22% on September 18.

By October 24, AIG had borrowed three-quarters of the rescue fund set up by the government. The money was used to write down the bad debts which AIG guaranteed for other firms' risky mortgage investments. The new CEO of AIG warned that the \$123 billion fund provided by the government might not be enough to keep AIG afloat.²⁸ Investors read this as a negative signal and the return was -21%. The bankruptcy chance was then very high at 35%.

On Sunday November 9, AIG received a \$150 billion government bailout to reduce interest payments and provide more time to sell assets.²⁹ The bankruptcy risk decreased to 3% on the next day.

²⁶ From <http://www.ft.com/cms/s/0/271257f2-83f1-11dd-bf00-000077b07658.html>.

²⁷ From <http://www.ft.com/cms/s/0/e91b24b6-8557-11dd-a1ac-0000779fd18c.html>.

²⁸ From <http://www.washingtonpost.com/wp-dyn/content/article/2008/10/23/AR2008102303352.html>.

²⁹ From <http://www.ft.com/cms/s/0/614586b4-ae9f-11dd-b621-000077b07658.html>.

On March 2, 2009, AIG announced a fourth quarter loss of \$61.7 billion, around \$23 per share, most of which stemmed from write-downs of credit default swaps and debt. AIG could access \$30 billion of new government capital and this prevented AIG from credit downgrades.³⁰ After two weeks, the bankruptcy risk for AIG gradually decreased and stayed at a low level.

CONCLUSIONS

We have developed a risk-neutral density model that uses options prices and estimates the chance of bankruptcy under a risk-neutral measure. The MLNbk model extracts RNDs more accurately than other RND models including a standard mixture of lognormals and a lognormal with a bankruptcy term. The resulting density shows the market expectation of stock prices over the lifetime of the options as well as the probability of bankruptcy over the remaining lifetime of the options. This information is forward looking, allowing investors and risk managers the possibility to estimate the chances of future bankruptcies.

We analyze in detail six major banks during the financial crisis period. As expected, when considering the forced merger cases we find a higher chance of bankruptcy for the acquired bank than for the acquiring bank. From analysis of the banks through key days in the financial crisis we see how the RND and probability of bankruptcy responds to news. We see that news announcements can have a significant effect on future bankruptcy probabilities as well as changing the shape of the RND. These case studies show in detail the information that can be obtained from option prices using the MLNbk model.

Finally, credit default swap prices provide similar and complementary information about risk-neutral perceptions of extreme future outcomes. Our RND models provide probabilities over short horizons, typically two months, in contrast to CDS probabilities for a year or more. We find that annualized measures of bankruptcy or default probabilities are higher from option

³⁰ From <http://www.reuters.com/article/GCA-CreditCrisis/idUSN0134457520090303>.

prices during the financial crisis, reflecting that any default is more likely in the next month or two than further into the future.

TABLES AND FIGURES

Table I Timeline of major events of financial institutions during financial crisis

Date	Event
17 Jan 2008	Lehman Brothers announced to cut 1,300 jobs. Merrill Lynch announced a \$7.8 billion loss.
11 Mar 2008	The Federal Reserve announced \$200 billion Term securities Lending Facility.
14 Mar 2008	The Federal Reserve provided a \$25 billion Loan to Bear Stearns.
17 Mar 2008	JP Morgan offered to acquire Bear Stearns at a low price.
24 Mar 2008	JP Morgan raised the acquiring price to \$10 per share.
28 Jul 2008	Merrill Lynch announced a \$8.5 share offer and a \$5.7 billion fire sale.
7 Aug 2008	AIG announced a higher than expected loss for subprime write-downs.
12 Aug 2008	JP Morgan Chase reported a \$1.5 billion write-down.
11 Sep 2008	Lehman Brothers announced to shrink its size.
15 Sep 2008	Lehman Brothers announced bankruptcy. Bank of America acquired Merrill Lynch.
16 Sep 2008	The Federal Reserve announced to lend AIG \$85 billion.
18 Sep 2008	The world's main central banks announced \$180 billion to improve liquidity.
26 Sep 2008	JP Morgan acquired Washington Mutual.
7 Oct 2008	Bank of America reported earnings which were less than analysts' expectations.
9 Nov 2008	AIG received a \$150 billion government bailout.
20 Dec 2008	S&P downgraded the rating of six major US banks.
15 Jan 2009	Bank of America received a \$138 billion bailout.
7 May 2009	A stress report shown JP Morgan was adequately capitalized; Bank of America lacked capital to survive in worst-case scenario.

Table II Sample periods, for estimating risk-neutral densities

<u>Institution</u>		<u>From</u>	<u>To</u>
Bear Stearns	BSC	July 2, 2007	May 30, 2008
JP Morgan	JPM	January 2, 2008	October 30, 2009
Lehman Brothers	LEH	January 2, 2008	September 12, 2008
Merrill Lynch	MER	January 2, 2008	December 31, 2008
Bank of America	BAC	January 2, 2008	October 30, 2009
American International Group	AIG	January 2, 2008	October 14, 2009

Table III Summary statistics for average, squared pricing errors for each institution

Distribution		BSC	JPM	LEH	MER	BAC	AIG
LN	Q1	0.1109	0.0238	0.0799	0.0473	0.0064	0.0182
	Median	0.1993	0.0580	0.1200	0.0789	0.0224	0.0455
	Q3	0.3996	0.1132	0.1972	0.1443	0.0569	0.1009
	Mean	0.3390	0.0837	0.2025	0.1378	0.0423	0.0714
	St. dev.	0.3928	0.0786	0.2881	0.1935	0.0537	0.0797
LNbk	Q1	0.0246	0.0055	0.0123	0.0073	0.0005	0.0019
	Median	0.0518	0.0129	0.0266	0.0149	0.0024	0.0121

	Median	0.0048	0.0012	0.0020	0.0012	0.0002	0.0007
	Q3	0.0091	0.0024	0.0045	0.0028	0.0011	0.0021
	Mean	0.0089	0.0023	0.0032	0.0026	0.0008	0.0020
	St. dev.	0.0160	0.0036	0.0036	0.0040	0.0014	0.0037
MLNbk	Q1	0.0008	0.0001	0.0003	0.0002	0.0000	0.0001
	Median	0.0016	0.0002	0.0006	0.0004	0.0001	0.0002
	Q3	0.0030	0.0006	0.0010	0.0008	0.0004	0.0007
	Mean	0.0027	0.0005	0.0010	0.0009	0.0003	0.0011
	St. dev.	0.0044	0.0009	0.0022	0.0019	0.0007	0.0021
First maturity used		3.6%	0.5%	2.2%	2.0%	2.0%	4.5%
Second maturity used		79.1%	77.8%	85.5%	83.8%	67.3%	73.9%
Third maturity used		17.3%	21.4%	12.3%	14.2%	30.6%	21.5%
Days with $N \geq 5$		196	463	179	253	447	330
Days discarded, when $N < 5$		35	0	0	0	15	119
Average value of N		18.9	18.0	17.3	17.8	12.9	18.8

The sample periods are listed in Table II. The summary statistics are for the quantity H defined by (9). N is the number of option prices used to estimate the parameters of the distributions.

Table IV Parameter estimates for the MLNbk distribution when $F_1 < F_2$

Parameter		BSC	JPM	LEH	MER	BAC	AIG
π_1	Mean	0.3665	0.3685	0.3408	0.3633	0.3815	0.4615
	Std. dev.	(0.18)	(0.13)	(0.11)	(0.12)	(0.19)	(0.26)
π_2	Mean	0.6216	0.6217	0.6216	0.6114	0.6010	0.4973
	Std. dev.	(0.18)	(0.13)	(0.13)	(0.13)	(0.19)	(0.28)
F_1	Mean	82.4566	31.6014	28.8626	28.4745	18.6043	23.6324
	Std. dev.	(31.93)	(8.11)	(14.63)	(13.02)	(10.47)	(16.29)
F_2	Mean	104.1070	40.8272	41.2492	37.7377	25.1432	31.7486
	Std. dev.	(40.80)	(6.73)	(17.29)	(15.27)	(12.39)	(20.75)
σ_1	Mean	0.6002	0.6278	0.9285	0.7714	0.6737	1.6802
	Std. dev.	(0.25)	(0.24)	(0.63)	(0.29)	(0.47)	(4.22)
σ_2	Mean	0.5776	0.3483	0.4642	0.4154	0.5120	1.5256
	Std. dev.	(2.72)	(0.13)	(0.22)	(0.20)	(1.56)	(3.55)
$1 - \pi_1 - \pi_2$	Mean	0.0119	0.0099	0.0376	0.0253	0.0176	0.0412
	Std. Dev.	(0.03)	(0.01)	(0.09)	(0.03)	(0.02)	(0.08)
F_1/F	Mean	0.8675	0.8381	0.7891	0.8421	0.8050	0.8823
	Std. dev.	(0.21)	(0.09)	(0.18)	(0.12)	(0.16)	(0.18)
F_2/F	Mean	1.0964	1.1045	1.1737	1.1409	1.1401	1.3454
	Std. Dev.	(0.21)	(0.06)	(0.14)	(0.10)	(0.17)	(0.65)

The sample periods are listed in Table II.

Table V Average percentage measures of bankruptcy risk

	MLNbk	CDS 1 year/2 mths	Period	Options lifetimes
JP Morgan	0.72	1.54/0.23	19 Feb. - 17 Mar. 2008	0.1504
Bear Stearns	3.12	10.53/1.60	19 Feb. - 17 Mar. 2008	0.1454
Bank of America	0.91	1.75/0.41	15 Aug. - 15 Sep. 2008	0.2333
Merrill Lynch	2.29	8.76/1.37	15 Aug. - 15 Sep. 2008	0.1506
Lehman Brothers	7.68	14.09/2.26	15 Aug. - 15 Sep. 2008	0.1506
AIG	3.76	12.51/1.91	15 Aug. - 15 Sep. 2008	0.1446

The tabulated probabilities are percentage averages across the month. The last column shows the average lifetimes of options (in years) used to obtain the MLNbk averages. The MLNbk probabilities are for the time until option expiry. The first CDS probability is for one year, while the second probability is for the option lifetime (assuming a constant default intensity across the next year).

The bankruptcy risk of acquiring banks

Figure 1: Bankruptcy risk of acquiring banks. The graph shows the risk neutral probability of bankruptcy, $1 - \pi_1 - \pi_2$ from the MLNbk model. Notable dates are included on the graphs for information.

The bankruptcy risk of acquired banks and other financial institutions

Figure 2: Bankruptcy risk of acquired banks and other financial institutions. The graph shows the risk neutral probability of bankruptcy, $1 - \pi_1 - \pi_2$ from the MLNbk model. Notable dates are included on the graphs for information.

Figure 3: Bankruptcy risks of BSC and JPM. The graph shows the risk neutral probability of bankruptcy, $1 - \pi_1 - \pi_2$ from the MLNbk model. Notable dates are included on the graphs for information. The estimated risk-neutral implied bankruptcy probabilities from senior 1 year CDS spreads are denoted by CDSbk.

Figure 4: Risk-neutral densities for Bear Stearns. These graphs show the risk-neutral densities on key dates during the forced merger between Bear Stearns and JP Morgan. Dashed lines denote MLN densities, solid lines denote MLNbk densities.

Figure 5: Risk-neutral densities for JP Morgan. These graphs show the risk-neutral densities on key dates during the forced merger between Bear Stearns and JP Morgan. Dashed lines denote MLN densities, solid lines denote MLNbk densities.

Panel A

Panel B

Figure 6: The bankruptcy risk and volatility of LEH. Panel A shows the risk neutral probability of bankruptcy, $1 - \pi_1 - \pi_2$ from the MLNbk model. Notable dates are included on the graphs for information. The estimated risk-neutral implied bankruptcy probabilities from senior 1 year CDS spreads are denoted by CDSbk. Panel B shows three measures of volatility: the realised volatility (RV), the conditional standard deviation from the GJR-ARCH model calculated from daily returns (GJR(1,1)) and the standard deviation of the MLN risk-neutral density (MLN). Again notable dates are included for information.

Figure 7: Risk-neutral densities for Lehman Brothers. These graphs show the risk-neutral densities on key dates during the collapse of Lehman Brothers. Dashed lines denote MLN densities, solid lines denote MLNbk densities.

Figure 8: The bankruptcy risks of BAC and MER. The graph shows the risk neutral probabilities of bankruptcy, $1 - \pi_1 - \pi_2$ from the MLNbk model for Bank of America (BAC) and Merrill Lynch (MER). Notable dates are included on the graphs for information.

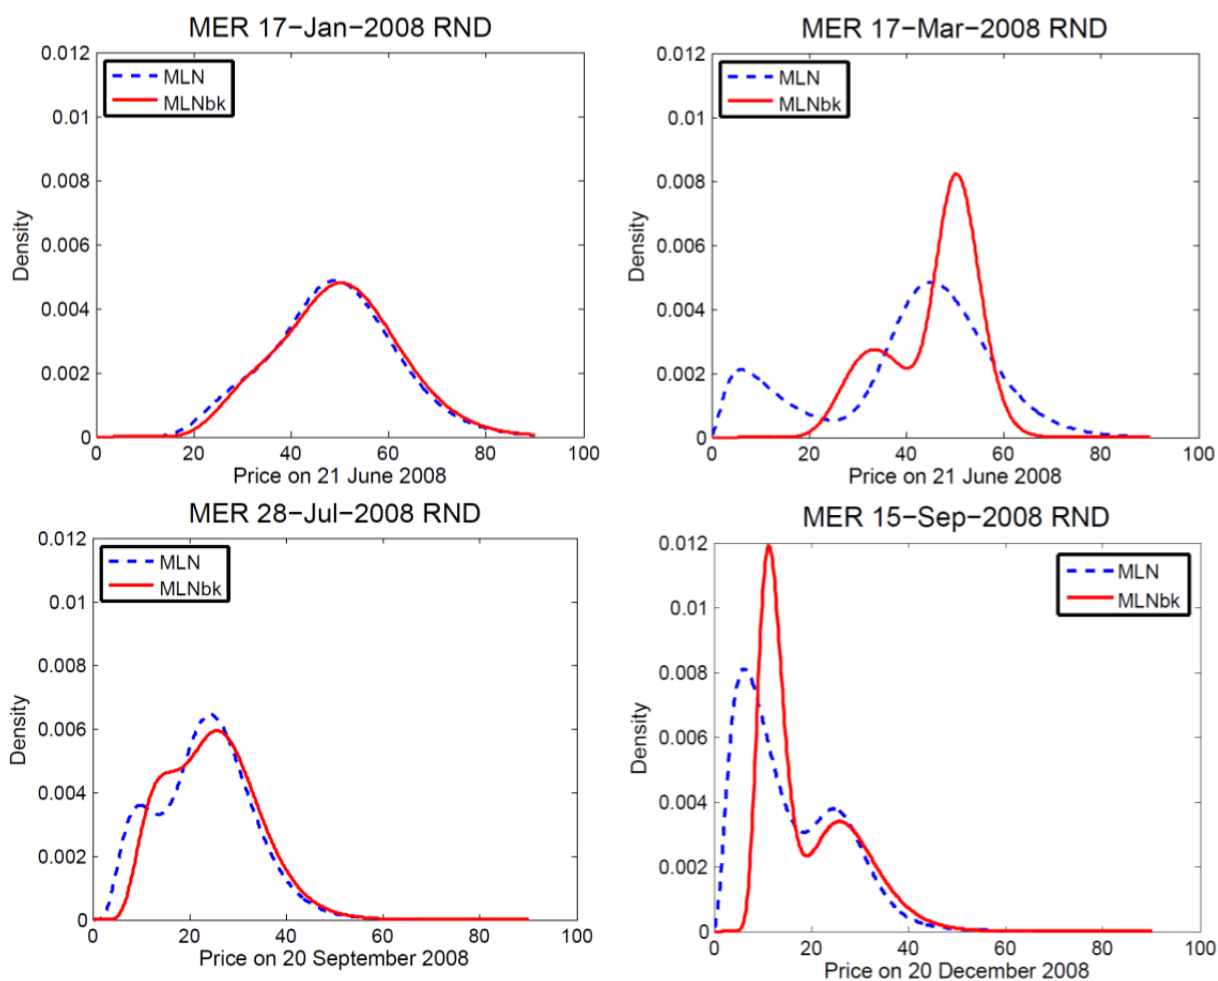

Figure 9: Risk-neutral densities for Merrill Lynch. These graphs show the risk-neutral densities on key dates during the forced merger between Merrill Lynch and Bank of America. Dashed lines denote MLN densities, solid lines denote MLNbk densities.

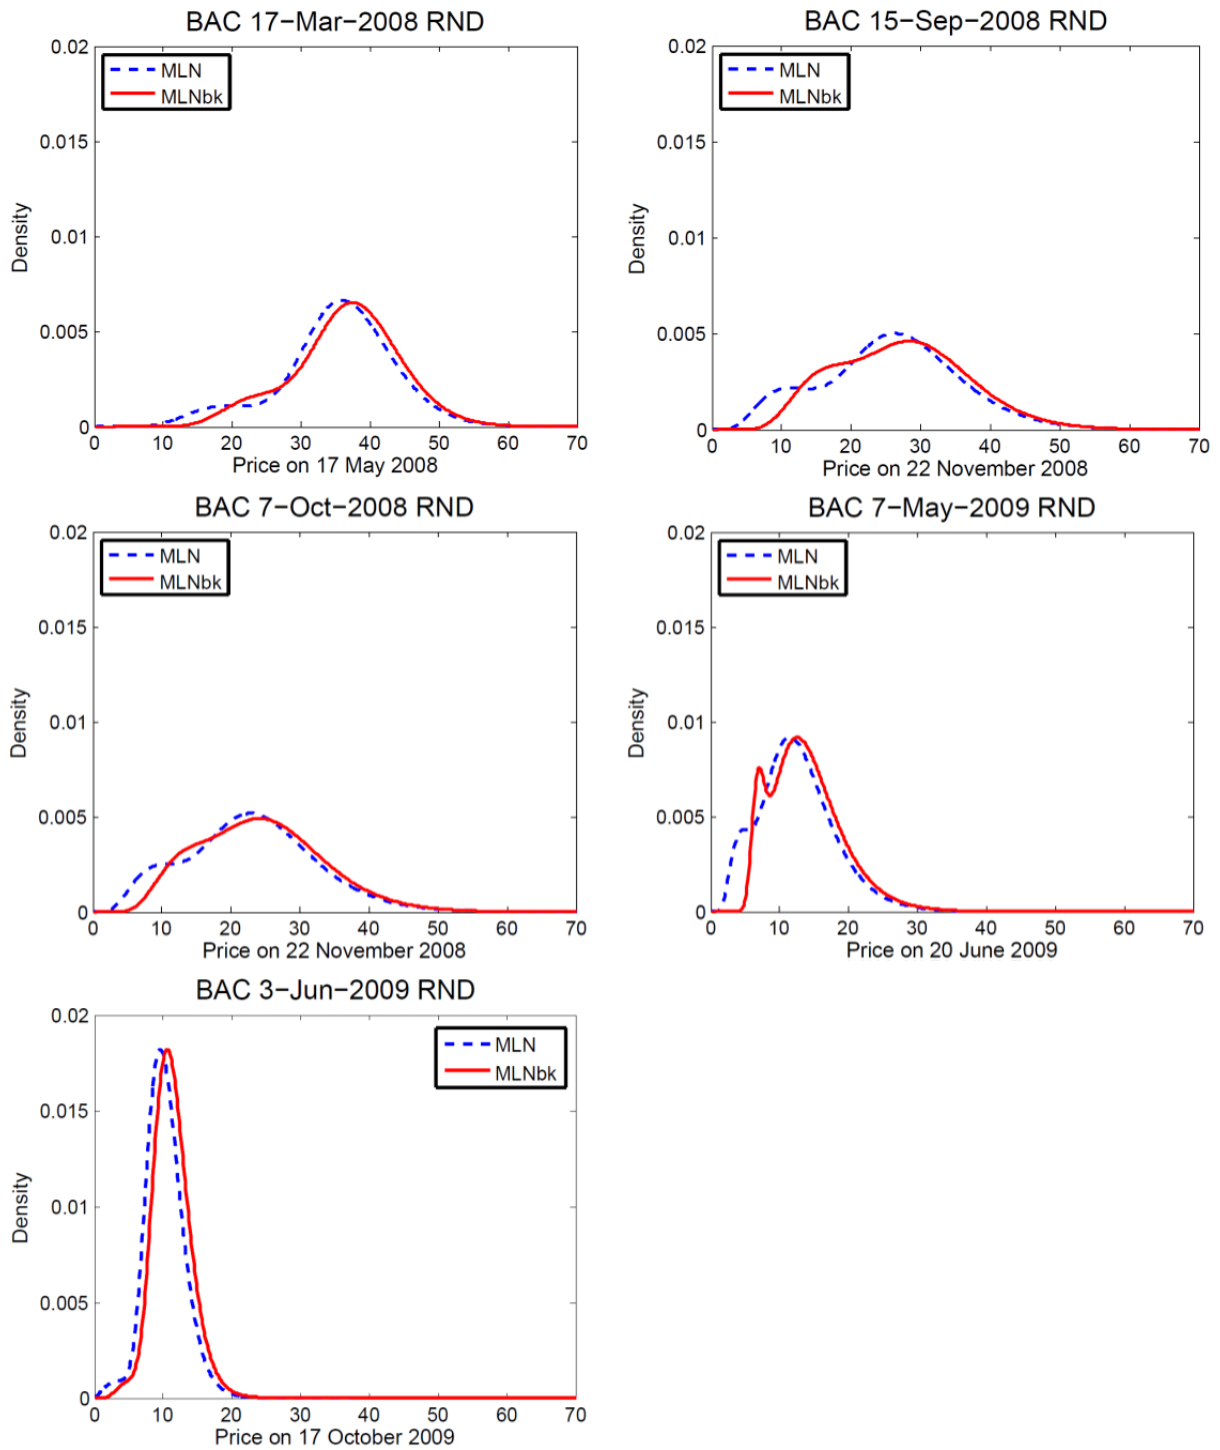

Figure 10: Risk-neutral densities for Bank of America. These graphs show the risk-neutral densities on key dates during the forced merger between Merrill Lynch and Bank of America. Dashed lines denote MLN densities, solid lines denote MLNbk densities.

Figure 11: Risk-neutral densities for America International Group. These graphs show the risk-neutral densities on key dates during the near collapse of AIG. Dashed lines denote MLN densities, solid lines denote MLNbk densities.
