## **ABSTRACT**

---

As a technology, additive manufacturing has remained largely unchanged since its introduction in the 1980's. However, advancements in computer aided design (CAD), the selection of available materials and more complex manufacturing requirements have allowed its value to extend beyond being a research tool into one that is capable of providing a financially viable and production feasible manufacturing solution.

Healthcare product innovation is currently a resource not being used to its full capacity within the healthcare sector in the UK [1]. Professionals within this sector often have ideas for technical innovation but the development is often thwarted due to a lack of engineering knowledge. In addition to this, the opportunities to develop these ideas are often limited through lack of time and resources.

It is the aim of this dissertation to show how healthcare professionals can advance their product ideas by utilising research facilities and additive manufacturing technology to produce proof-of-concept models for evaluation purposes.

It is integral to the development of an innovative product to be able to explain the value of an idea to external stakeholders. One method by which to achieve this is to produce concept designs and/or prototypes. Additive manufacturing technology is ideally suited to this because it can allow the rapid development of a concept which can then be used to produce a 3D model to aid the healthcare professional in relating their idea(s) to others.

The dissertation uses four case studies to show how the utilisation of additive manufacturing technology and design for additive manufacturing principles can be used to advance the early-stage development of new healthcare devices.

## **RATIONALE**

The purpose of the activity undertaken within this dissertation, was to study and explore how additive manufacturing (AM) technology could facilitate the development of products for the medical industry. The study focuses upon the initial prototyping and development of medical devices. By definition a medical device is any instrument or apparatus which is intended by the manufacturer to be used for the treatment of human beings. This can range from diagnosis e.g. laboratory equipment to disinfectant substances used in a surgical theatre. [1]

Chapter 1 introduces additive manufacturing technology which is defined as the process of creating 3D parts from computer generated models, the manufacture of these parts is achieved through the addition of layers of material as opposed to conventional subtractive manufacturing [2], and details how it is currently used in industry. This includes a review of three of the most prevalent AM processes: Stereolithography, Selective Laser Sintering and Fused Deposition Modelling. This was enabled by an analysis of how AM technology is currently utilised within the Automotive, Aerospace, Healthcare & Medical industries. The chapter predominantly focuses upon current uses of additive manufacturing technology within a research environment. This aims to highlight how National Health Service is being readily utilised to achieve rapid product development and proof of concept of non-medical devices. It is the purpose of this chapter to show that additive manufacturing could be used to provide proof of concept of medical devices. This chapter concludes with a section which discusses how universities can work with medical professionals to achieve accelerated product development through the utilisation of additive manufacturing.

Chapters 2 to 5 contain four individual case studies which were presented for consideration by medical and non-medical professionals to the author. Each of the studies explored how additive manufacturing could be utilised to reduce the amount of time between concept generation and final production by providing proof of concept designs and prototype models. The studies achieved this by using computer aided design and additive manufacturing technologies.

The main driver for this study was the rationale that National Health Service surgeons, consultants, clinicians and nursing staff often require access to an effective engineering design service. With such a service, they would be given access to engineers and additive manufacturing equipment so that they can develop their medically based product ideas. A service of this kind may benefit the wider population by increasing the efficiency and effectiveness of the National Health Service. The study expanded from this rationale to also include medically based ideas from non-medical professionals.

In conclusion, the study achieved the advancement of four concept ideas and provided a proof of concept for each. Each of the case studies included within this thesis constitute an initial research phase of medically linked projects, In three of four cases these projects have been developed further either by dedicated PhD projects or used in grant funding proposals.

# 1 INTRODUCTION

## 1.1 What is Additive Manufacturing

Additive Manufacturing (AM) is the current term used to describe a manufacturing method originating from the 1980's [3] which was initially called Rapid Prototyping (RP) [4]. The original term described the use of the technology, not the mechanics of the process. The main function of AM in its infancy was to develop prototypes and provide proof of concept which is still a very valid use today. However, the technology has now expanded into the manufacture of consumer goods, tooling and functional parts for many industrial sectors. AM is a more apt description as it fundamentally refers to the stacking of layers of material with a defined thickness (dependant on the machine specifications) vertically in the Z-axis. This is enabled by firstly creating a 3-Dimensional (3D) model, which is generated through the use of either computer aided design (CAD) software or 3D scanning data. This file can then be converted into a standard tessellation language file (stl) to allow the AM machine to interpret the model (other formats are also used, they are briefly discussed later in the study). The geometry of the 3D model is converted into a mesh of triangulated surfaces which are mapped using a 3D Cartesian coordinate system. A by-product of this is that whilst the file is correctly proportioned, there is no scale or measurement unit information.

Within the activity discussed in this dissertation, stl files are used exclusively; the geometries created within this study did not require a more advanced file type. More advanced file types such as the Additive Manufacturing File Format (amf) [6] or 3D Manufacturing Format (3mf) [7] are utilised in AM machines which are capable of fabricating components in multiple colours and/or different materials, such as the Stratasys J750 [8]. These newer more advanced file types are among many others which allow for more detailed models to be generated. The extra details include but are not limited to: material type and colour [5]. The amf format was released in 2011 and not only allows for colour and material information, but also has the capability to incorporate curved triangular patches which improve the geometric fidelity of a part. In turn, this provides a significantly more customisable and complete part. After the file is processed, it can be transferred to the AM machine, where it is deconstructed into layers of a specific thickness dependent upon the capability of the machine. The AM machine then builds the model one layer at a time in the Z-axis.

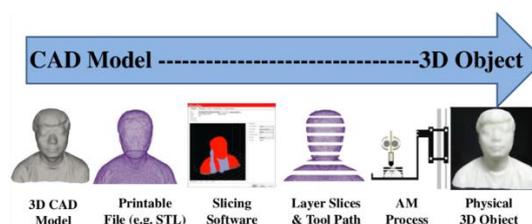

Figure 1: General process of AM [9]

Some processes, such as Fused Deposition Modelling (FDM) require support material for angles of  $+45^\circ$  in order to facilitate the printing process [10]. Also discussed in this dissertation is

Stereolithography (SL) which utilises support structures and Selective Laser Sintering (SLS) which is self-supporting.

## 1.2 Additive Manufacturing Technologies

There are many different types of AM technology. Some require support material in order to achieve complex geometries, whereas others can achieve this without the need for support structures. It is significant distinctions such as this which help to categorise the different types of AM. Generally, AM can be grouped into four categories based upon the material state: liquid, filament, powder and solid sheet. However, the American Standards Organisation ASTM subcategorises AM technology into seven segments detailed in Table 1 [11, 12].

<b>Process category</b>	<b>Technology</b>	<b>Material</b>
Vat Photopolymerisation/liquid polymer	SL	UV curable resins
Material Jetting	MJM (MultiJet Modelling)	Waxes Ceramics UV curable resins
Binder Jetting	3DP (3D Printing)	Waxes Composites Polymers Ceramics
Material Extrusion	FDM	Thermoplastics
Powder Bed Fusion	SLS SLM (Selective Laser Melting) EBM (Electron Beam Melting)	Thermoplastics Metals
Sheet Lamination	LOM (laminated object manufacturing)	Paper Metals Thermoplastics
Direct Energy Deposition	LMD (Laser Material Deposition) LENS (Laser Engineered Net Shaping) EBAM (Electron Beam AM)	Metals

**Table 1: Additive manufacturing subcategories [11]**

There are three types of AM utilised in this study, these were chosen as they were the AM technology types available at the Lancaster engineering department laboratories. A brief description of these processes are given below, and each is concluded with a technical specification of the specific machine that was used in achieving the production of prototype models for the case studies that are described in subsequent chapters.

### 1.2.1 Stereolithography

Stereolithography (SL) as a term was used by 3D systems in 1986 [10]. The term briefly lost its specificity in the 1990's where it became a catchall term for AM. The proliferation of FDM in subsequent years in the hobbyist market helped SL reclaim its individuality as a term.

SL uses ultraviolet (UV) laser light to cure photosensitive polymers. A vat of resin sits above a UV laser and a build plate is initially submerged within the resin. The laser then traces the desired path which is specified for the first layer of the build. After each layer has been cured, the base plate will index away from the resin so that the previous layer's cured structure is all that is submerged within the uncured resin vat. This process is repeated until the build is complete. The information provided to the SL machine is often in stl format, the machine converts this, first into layers and then into X, Y toolpaths and the desired Z index [14].

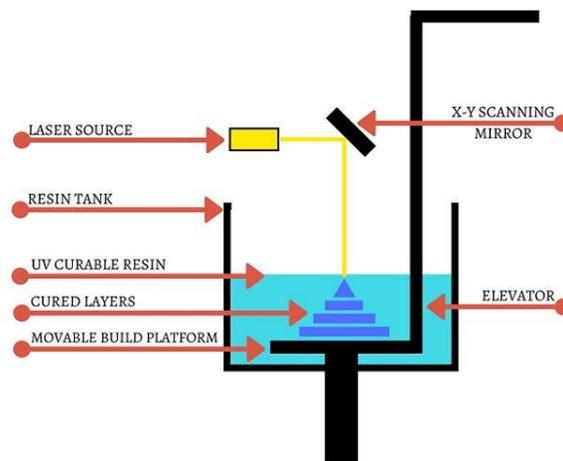

Figure 2: Overview of SL technology [15]

SL is a high resolution method of AM, the layer height is generally in the region of 25 – 100  $\mu\text{m}$ . In laser systems, the thickness of the layer is not determined by the index distance of the Z axis, instead the index height is based upon a relationship between the intensity of the UV laser light and the scanning speed. The Z axis index distance is dependent upon the intensity of the laser light because the more intense the light or the slower the scan speed, the greater the penetration depth. This relationship is described mathematically as such:

$$C_d = D_p \ln (E/E_c) \quad (\text{Eq. 1})$$

Where:

$C_d$  = Cure depth (mm)

$D_p$  = Penetration depth (mm)

$E = \text{Irradiation dose } \text{mJ}/\text{mm}^2$

$E_c = \text{Gel point } \text{mJ}/\text{mm}^2$

The equation describes how the cure depth increases logarithmically with time. The gel point is specific to each polymer, as the gel point is exceeded by the irradiation dose the cure depth increases [16].

There are disadvantages to SL method, one of which being the storage of resins. Unlike the filament used in FDM and the powder used in SLS, the photosensitive resins perish in sunlight which means that the quality of the resin decreases the more it comes in to contact with light [14]. Some contact with light is highly probable when setting up a build, during a build and during the builds post processing stage. These factors have to be taken into consideration when utilising a photosensitive resin.

An advantage of SL over its FDM and SLS counterparts is the resolution of the parts it can produce. The higher resolution results in a more accurate final product when compared with FDM in particular. The resolution is determined by the focal diameter of the laser which in general is a degree of magnitude small than the aperture of an extruder head. Further to this, the resolution is a product of the cure depth of the system, the lower the cure depth the greater the resolution.

### 1.2.1.1 Form1 - Form Labs

An example of SL AM technology is the Form 1 (Figure 3), which applies SL technology whereby a laser cures each layer of the photopolymer resin as the bed indexes in the positive Z direction. This technology was used as it was the highest resolution AM machine available at the Lancaster engineering department laboratories at the time of conducting the research in this study.

#### Technical Specification

<b>Technology:</b>	Stereolithography
<b>Material:</b>	Photoreactive Resin [15]
<b>Build Volume:</b>	125 x125 x165 mm
<b>Layer Resolution:</b>	25, 50, 100, 200 microns
<b>Laser Spot Size:</b>	155 microns

Figure 3: Technical specification of the Form1 3D printer [18]

### 1.3 Fused Deposition Modelling

As a layer addition process, FDM utilises production grade thermoplastics to create parts, which can be either fully finished end-use products or functional prototypes.

FDM is the main AM technique that is utilised by hobbyist machines. This is due to the relatively low cost of the machines themselves and the materials. The materials used in FDM range from standard Acrylonitrile Butadiene Styrene (ABS) or Polylactic Acid (PLA) to much more exotic materials such as Carbon impregnated ABS.

The process of FDM begins in the same way as the other methods of AM within this study in that it begins with the slicing of 3D CAD data into layers. This data is then processed by the machine, which converts the slices into a toolpath for the extruder head. A toolpath is produced for each slice on the XY plane. Following the completion of the toolpath the machine then indexes a distance in the Z direction based upon the thickness of the extruded material.

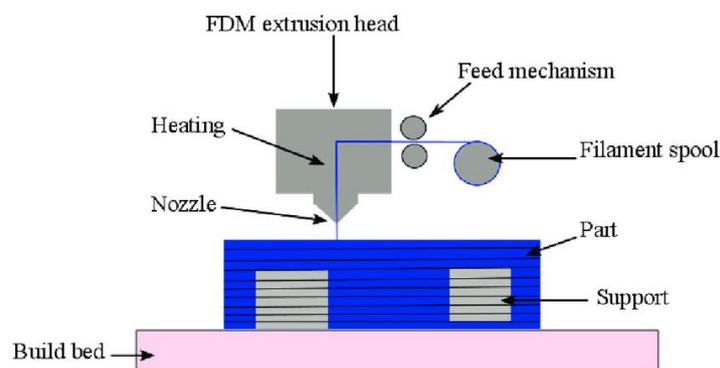

Figure 4: FDM process overview [22]

The thermoplastic is extruded through a heated nozzle and precisely deposits material following the generated toolpath. The accuracy in this plane is dependent on the quality of the machine's linear axis. One advantage of FDM is that it is relatively accurate in the XY, compared with selective laser sintering.

The resolution of FDM printers tends to be larger than that of SL and SLS.[23] This results in a more pronounced stepping effect on the parts it produces. It is important to take this into account when building models using this method because actions can be taken to minimise its effect. Stepping is particularly pronounced within the FDM process due to its typically larger layer thickness. An analysis of where the required part needs to be accurate should be carried out. For example, a cylindrical bush is to be manufactured to have a tight tolerance fit with a shaft. The bush could be printed vertically, horizontally or any angle in between. However, to produce a highly accurate part, the cylinder must be printed horizontally. In this orientation, the FDM machine will stack layer upon layer of 2D circles atop one another. This means that the part is of the highest possible accuracy across its diameter and of the lowest accuracy in its length.

Figure 5: Illustration of cylinder print orientation [24]

FDM is advantageous over SL and SLS in many ways. The material used is cheaper, the process is faster and large FDM machines are available to facilitate the production of large models. However, FDM has disadvantages also, such as layer delamination, requirement for support material, (this can make parts less economical to produce because more material is used and more energy has to be used to extrude this extra material). And FDM also typically cannot achieve the resolution of its SL and SLS counterparts [25].

FDM parts have a distinctive stepped appearance. The parts can be post processed to produce a smooth finish utilising:

- Chemicals such as acetone, which dissolve the outer layer of ABS parts;
- Abrasives such as fine grade sandpaper, used to physically smooth a part;
- Resins such as two-part clear epoxy resin, this is used to fill the steps, the part can then be polished to achieve a smooth finish.

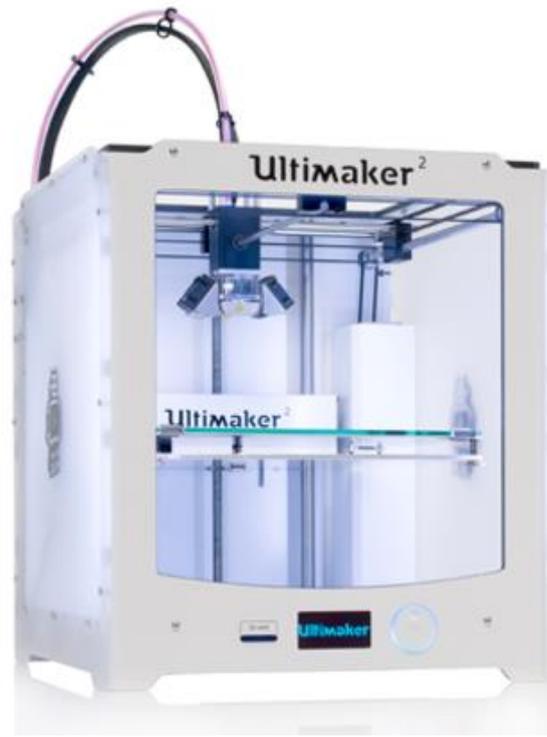

Following these methods, a part can be painted to achieve a desired level of finish.

#### 1.3.1.1 *Ultimaker 2 –Ultimaker*

An example of FDM AM technology is the Ultimaker 2 (Figure 6). In brief, the Ultimaker utilises a thermoplastic (usually PLA or ABS) which is heated to its glass transition phase (material specific temperature) within the extruders 'hot-end'. It is then extruded onto the heated bed which indexes in the negative Z direction. This is repeated as many times as necessary in order to produce the completed product.

This technology was used as it was the highest resolution AM machine available at the Lancaster engineering department laboratories at the time of conducting the research in this study.

## Technical Specification

<b>Technology:</b>	Fused Deposition Modelling (FDM)
<b>Material:</b>	ABS, PLA etc.
<b>Build Volume:</b>	223 x223 x205
<b>Layer Resolution:</b>	20-600 microns
<b>Build Speed:</b>	24 mm <sup>3</sup> /s

Figure 6: Technical specification of the Ultimaker 2 3D printer [26]

### 1.3.2 Selective Laser Sintering

Selective Laser Sintering (SLS) is a form of additive manufacturing technology which utilises a laser to raise the temperature of precise regions of a powdered polymer to its glass transition phase.

The process involves slicing 3D CAD data into 2D layers, the 2D layers are imported into the AM machine where each is generated into a toolpath for the laser. The build area is heated to reduce the amount of energy required of the laser to heat the powdered material to sinter point. The temperature is maintained through the use of infrared heaters. The build base indexes downward after each pass of the laser. The powder is then replenished by two powder feed cartridges which index upwards, these bins are serviced by a counter rotating roller which travels horizontally thereby distributing a layer of powder across the build area. Each new layer of powder is approximately 0.1mm thick [4].

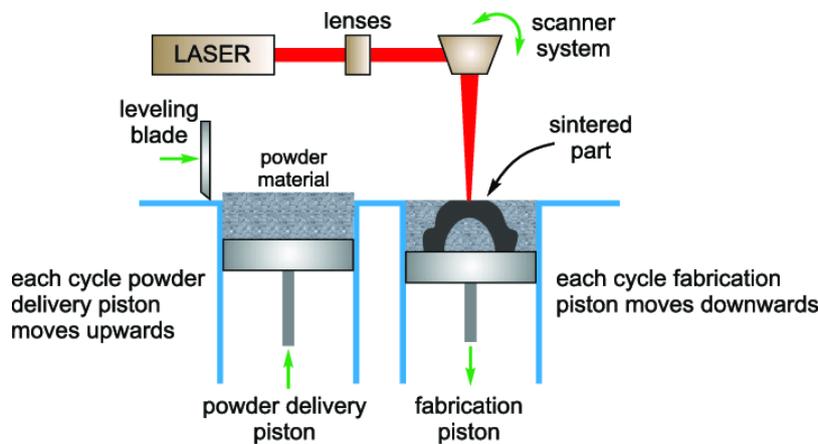

Figure 7: Overview of SLS technology [27]

The chamber is filled with an inert gas to limit the amount of oxidation of the powdered material during the sintering process.

SLS parts are susceptible to warping which is due to the power imparted by the laser and non-uniform distribution of heat within the chamber. The longer the laser is active the greater the energy dispersed within the powder, this means that a warped part with a poor surface finish may be produced. It is for this reason that the temperature of the build area and the duration the laser is activated is important. The duration that the laser is active within each layer can be minimised with careful planning of the build stack. Following a successful build, the chamber is allowed to cool uniformly. If the parts are prematurely removed from the chamber thereby being exposed to cooler ambient temperatures, they can warp due to irregular thermal contraction [4].

One major advantage to SLS in comparison with SL and FDM is the lack of need for support structure as the powder itself supports the component being built. This in turn allows for assemblies with tight tolerances to be produced together on the same build. In industry this would improve production time by minimising the need for a fabrication stage.

A disadvantage is the surface finish of SLS parts. The parts have a poor surface quality when compared to conventionally machined parts (The surface roughness of an SLS part can be in the range of

28~35µm. [28]); however, this can be overcome with the application of appropriate post processing methods such as sanding, followed by painting. SLS parts can be geometrically more complex than FDM. For example, SLS can facilitate the production of parts with almost totally enclosed voids (with the exception of a small hole to allow the excess powder to be removed). The powder that supports the structure of the void can be removed through a comparatively small hole in the structure which is easily sealed to complete the desired internal void. This cannot be achieved as easily with FDM and SL because the support structure is larger.

From the discussion (above) which outlines some AM technologies, it can be concluded that SLS has benefits in that it allows for geometries that are not possible with the FDM and SL methods. However, parts can have poor geometric accuracy because of the possibility of part warpage due to laser over exposure and irregular heat distribution.

### 1.3.2.1 *Sinterstation 2000 from 3D Systems Inc*

An example of a SLS machine is the Sinterstation 2000 (Figure 8) which is an industrial machine using an 50Watt CO<sub>2</sub> air cooled laser to raise the temperature of specific areas of a powder layer to just below melting point. Nylon 12 was the material used to build some of the prototype models for the case study applications discussed within this dissertation.

#### **Technical Specification**

<b>Technology:</b>	Selective Laser Sintering
<b>Material:</b>	Nylon-12 (powder)
<b>Build Volume:</b>	320mm (diameter) x 380mm
<b>Layer Resolution:</b>	.25mm

**Figure 8: Technical specification of the Sinterstation 2000**

## 1.4 Current uses of Additive Manufacturing

AM is currently used across a wide range of industrial sectors and for varying applications. Despite it being highly useful in producing complex geometries, it isn't necessarily the solution to all manufacturing problems as later discussed. AM is being used for batch production, tooling creation and prototyping and certainly is an enabling technology as manufacturing moves towards automation and mass customisation.

Three major industries which are currently utilising AM, and discussed in more detail below, are Aerospace, Automotive and Medical. These industries have been chosen to show how AM is used in high value/ low volume industries, this aligns with the general theme of this study.

### 1.4.1 Aerospace Industry

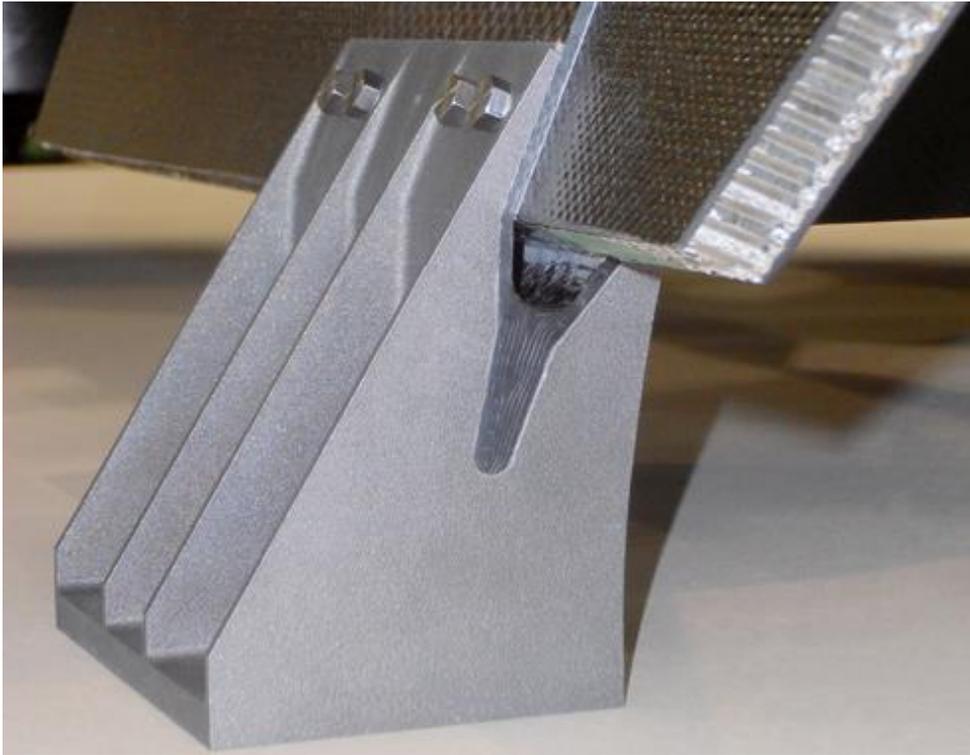

The aerospace industry is utilising AM to realise parts that have high geometric complexity and highly complex functionality. For example, the integration of honeycomb internal structures whereby small air pockets within a part allow it to be lightweight yet structurally capable. Furthermore, AM provides the ability to create complex cooling channels that allow liquid to flow through a thermally dependent part and thus maintaining the parts correct operating temperature. Complex cooling channels would be either impossible or very costly to manufacture conventionally.

Polymer AM parts are already being used within military aircraft [10], but metals such as titanium will be utilised more and more in coming years due to its high strength to weight ratio and the development of machines capable of processing it such as SLM and EBM.

The Airbus Space and Defence Division specialises in the production of parts for satellite systems. In 2014 they encountered a problem with the titanium retaining brackets used to fix composite panels to a satellite's structure. The brackets were manufactured using conventional means which meant that the geometry of the bracket was dictated by Design for Manufacture (DFM) criteria rather than geometry that was optimised to reduce stress around the panel-bracket interface [29].

With conventional manufacturing deemed as unsatisfactory for these reasons, an AM solution was sought. CAD and Finite Element Analysis (FEA) allowed for an optimised part to be designed that was, crucially, not hindered by the need to subscribe to DFM criteria. Further to this, the part was then able to be constructed in one step (Figure 9), rather than multiple stages as is common with conventional manufacturing of metal parts.

A disadvantage of AM in the aerospace industry is the strict regulation surrounding material properties and the predisposition of the industry to use tried and tested methods of production, particularly for structural components.

**Figure 9: AM bracket utilised in the aerospace industry [29]**

#### 1.4.2 Automotive Industry

Automotive manufacturers have used AM to gain a competitive advantage over other car manufacturers as it is used as a bridge-tooling process. A bridge-tooling process can be defined as the production of a part as a placeholder until an end-use part can be manufactured [10].

In the Formula Student competition 2012, Stuttgart University utilised AM to produce a topology optimised steering stub axle. The challenge was to use AM to improve the performance of a part that was being manufactured using high precision casting. The rationale was stated that although the current part functioned well, it was limited by its subscription to DFM criteria [13].

AM allowed for an optimised design to be prepared and manufactured with a short lead time (Figure 10). This is crucial in a competitive motorsport environment in order to produce products rapidly to keep up with the competitive market. The weight of the final part was reduced by 660g (approximately 35%) with a 20% increase in rigidity [30].

A disadvantage for the use of AM in the automotive industry is that the automotive (in general) produces high volume parts. For high volume parts, traditional methods are more cost effective. E.g. injection moulding.

**Figure 10: AM bracket utilised in the automotive industry [30]**

### 1.4.3 Medical industry

The Medical industry is an area of particular importance for AM with regards to how it has the potential to drastically improve the wellbeing of patients. One major component to which this collaboration is hinged is the ease at which medical imaging data (e.g. Magnetic Resonance Imaging (MRI) and Computerised Tomography (CT)) can be converted into a 3D model [31].

For example, a 3D model of a patient's injured mandible could be used to create a surgical guide tool. This tool enables a surgeon to complete a surgery quicker and in a more efficient manner. Any surgical method or tool that reduces a patient's time under anaesthesia and overall surgery time is highly valuable.

The accuracy of AM models produced using CT and MRI images has been scrutinised in studies conducted by Mika *et al* [32] concluded that Polyjet technology [10] was the most accurate with a percentage error of  $\pm 0.12\%$  and 3DP to be the least accurate with a percentage error of  $\pm 0.43\%$  [33]. A study conducted by Diethard *et al* [44] focused on image scan process parameters, in order to investigate how to optimise a CT or MRI scan for fabrication of AM models. The study concluded that medical images required a degree of pre-processing to produce an accurate model. It was important for this study to confirm the suitability of medical images for the production of AM models to ensure the validity of the case study discussed from Chapter 3.2.

Surgical tools in general could benefit from AM. For example, a surgeon who is an expert at using the current tools available to perform a surgery, could drive the advancement of more sophisticated tools through the application of AM principles.

It can be postulated that a surgeon who specialises in a particular type of surgery has the knowledge to improve surgical tools but possibly doesn't have the necessary engineering knowledge to bring any improvement ideas to fruition. Collaboration with a research institution could help combine two areas of expertise (engineering/medical) to allow for an accelerated route to manufacture [3]. AM could help provide the proof of concept that is crucial when attempting to attract investment. This would allow the medical professional to drive new technologies by utilising resources that were not previously available to them.

AM can be used to produce 3D models of a patient's ailment. For instance, if a patient has a brain tumour, AM can be used to recreate a model of it. The benefit of this is that it can be used in conjunction with counselling to give a patient empowerment and ownership over their condition. MRI and CT scans can be shown to patients but they are difficult to interpret, so difficult in fact that the interpretation of them is a medical specialism: Radiology. A radiologist specialises in the modalities of medical imaging which include MRI, CT ultrasound (UT) and nuclear medicine (NM), in order that a patient can develop an understanding of their condition. Viewing their medical images falls short of the mark due to its vague and uninformative nature to the untrained patient. This is where AM can be of use as a physical, 3D representation of a condition could provide a patient with the empowerment of more complete understanding [35].

The process detailed above has taken place in a children's hospital in Phoenix (USA). A patient was found to have a benign but growing brain tumour. The tumour was removed and a 3D replica was made which helped with the healing process (Figure 11). One recipient stated "I could see how big it was and how the shape was, so I could see what was inside my head at the time" [35]. Another said "Lock it in a box and put in your drawer or destroy it with a hammer, you can do that, so it gives you both a physical and psychological outlet" [35]. A small change in how an illness is approached can make a positive difference in how a patient copes.

**Figure 11: Additive manufactured representation of a brain tumour [35]**

## 1.5 Examples of Additive Manufacturing in a Research Environment

AM has particular importance within research facilities such as the Lancaster Product Development Unit (LPDU) and the Advanced Manufacturing Research Centre – Integrated Manufacturing Group (AMRC - IMG) which utilises FDM to speed up its concept realisation. An example of this is in the production of housing for an active RFID tag produced by Ubisense. The tag transmits a radio signal to sensors which are located around the circumference of the AMRC's Factory 2050 building.

The sensor records the angle of arrival and time of flight of the signal sent out by the tag. From this, provided that the tag is visible by two or more sensors, the position can be triangulated to within  $\pm 150\text{mm}$  of its actual position. The driving force behind the use of the Ubisense system is asset tracking. It is increasingly important within the aerospace industry, and indeed in general manufacturing, to know where parts are so that the time to completion can be calculated and resources assigned. In this case, two sensors needed to be housed on an Automatically Guided Vehicle (AGV) so that not only could it be tracked but the orientation could be deduced and displayed on a real-time dashboard.

AM enabled a housing of this type to be prototyped rapidly, which went through a design iteration within one working day. This speed can't be achieved by traditional methods and is important in ensuring that a successful end use part is developed and useable quickly (Figure 12A-12F).

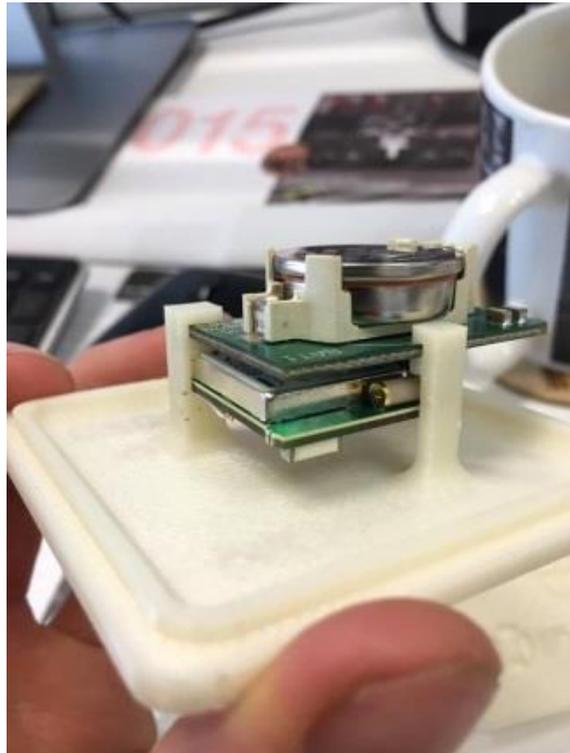

Figure 13(A-C) shows the development of a Mk2 version which holds the sensor more securely through the addition of slots which match the form factor of the tracking device.

A

**B**

**C**

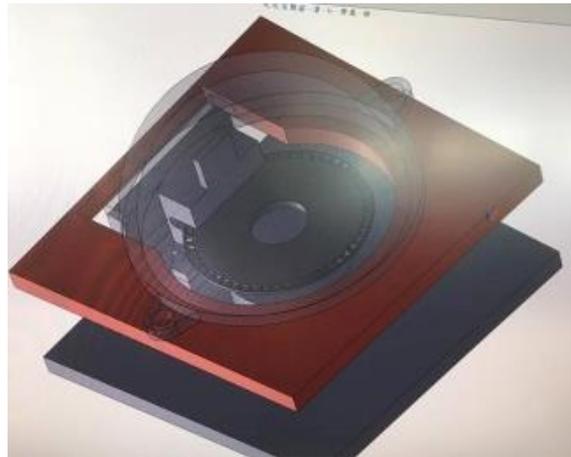

**Figure 13: Development of the device in the previous figure**

A further example of this is given in Figure 14(A-D), where FDM was used to create the housing for an optical encoder. The encoder was used to measure the linear motion of a rack within a sealant distribution tool. The encoder enclosure had to match the curvature of the device to ensure that the

encoder disk was isolated from the working environment. This allowed for consistent measurement of the linear motion of the tool as shown in the image below.

A

B

C

D

Figure 14: Design of an enclosure in a research facility

From the above examples provided above, it is clear to see that AM is invaluable in a research environment for its ability to rapidly visualise designs, assess form-fit-function and to optimise the design through an iterative process.

## 1.6 Disadvantages of Additive Manufacturing

There are some major drawbacks to AM which have hindered its advance into industry, namely:

**Time:** AM can be considered slow in comparison to high speed machining, which can remove material much faster than an AM machine can add it. Further to this, AM is hindered by its previous moniker 'Rapid Prototyping' as it is assumed to be more or less an instant fabrication process. This is not the case; a stacked build on a Sinterstation for example can take upwards of 60hours to complete. Time per part might be relatively low, but overall time is in excess of the expectations of non-technical people, such as business managers. However, what must be considered is that machining is often just one stage in the manufacturing process whereas AM can be considered in some applications as single stage production.

**Accuracy:** Dimensional accuracy is best along certain axis, for example in FDM the best resolution is in X and Y because these are determined to a large extent by the accuracy of the machine, while Z has inherent inaccuracies associated with the interaction of each layer. [36]

**Mechanical Properties:** The layering of multiple interfaces can introduce undesirable mechanical properties. Each layer of material is a potential failure mode; this physical characteristic can cause parts to exhibit mechanical failures that are not characteristic of its material properties. [37]

## 1.7 How Additive Manufacturing Can Encourage Innovation

Innovation can be encouraged through the exploitation of AM. Conventional manufacturing methods require expensive tooling. The cost of the tooling is made economically viable by mass production of non-customised products. For example, a simple plastic car made through the conventional means of injection moulding would use a mould tool. The tooling for this process is expensive but, the cost of the mould is spread across the number of cars produced. This makes it economical for businesses and therefore injection moulding is almost always preferable for mass production of generic non customised parts. Conversely AM is ideal for one-off and sometimes batch production. It is particularly desirable if parts are to be used for prototyping and to demonstrate proof of concept.

It can be seen that mass production stifles customisation through the need to make a product easy to manufacture and the need to make it standardised. AM allows for customisation at a realistic margin (low volume/high value), thus allowing for innovation to be explored.

## 1.8 University Collaboration with Industry

### 1.8.1 Medical Industry

The design and development of medical devices is essential for the improvement of healthcare services, in particular for the NHS where the demand for products to manage, prevent and treat illnesses in the UK is set to increase with the increasing general and geriatric population. According to the Office for National Statistics, the proportion of the UK's population aged 65 and over will increase from 17.9% in 2014 to 22.9 in 2033 [38]. The prevalence of long-standing illnesses which require medical devices is closely linked with age; the strength of this relationship is alluded to by the statistic which states that people aged 75 or over are five times as likely to have a long term illness than those aged between 16 to 24 [39]. In addition to this, it can be hypothesised that the rise in sedentary and unhealthy lifestyles adopted in the UK will further perpetuate the need for healthcare devices to manage conditions in younger patients, such as diabetes and heart disease etc. An indication of the financial size of the market is the UK's expenditure on the national health which in 2012 reached £144.5 billion [40] and the projected size of the Western European medical device market which increased from \$73.11 billion in 2010 to \$103 billion in 2015 [41].

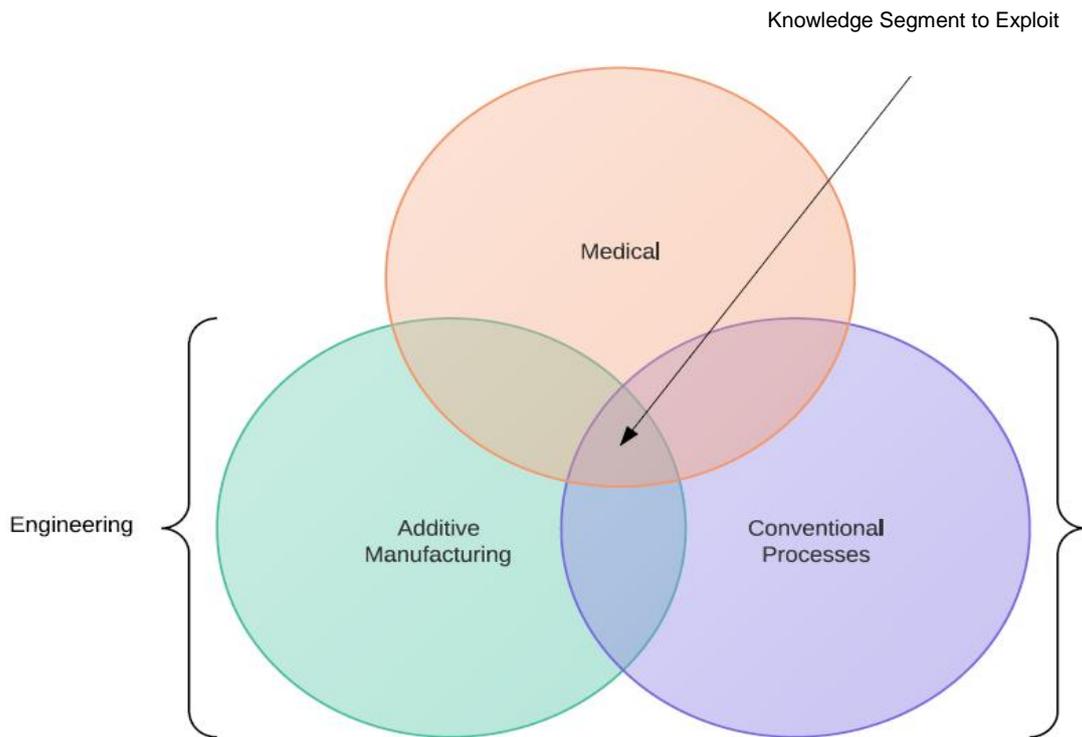

The demands faced here can be met in part through the innovation and creation of new medical devices. A need or area for improvement can often be identified by a physician but while they have expertise in the medical field, they often lack the engineering knowledge to develop their ideas into useable products, engineers have this knowledge and are able to translate an idea into a product.

The NHS requires innovation in order to be successful and provide the best patient care, so it is the aim of this dissertation to understand (through case studies) how an initial concept, formulated by a NHS physician, can be realised through AM methods.

Physicians have in-depth knowledge about the needs of patients with respect to medical devices and can identify areas in which they can be improved but they lack the engineering knowledge to create the devices or even to fully convey their ideas in a technical way.

Engineers using conventional subtractive and formative methods have the technical knowledge to convey ideas and to design devices based on information from a physician but they are limited by DFM criteria which leads to a product that has potentially compromised functionality.

Engineers utilising AM methods can provide proof of concept for a medical device without compromising the design of the device. Figure 15 illustrates how these differing elements all interact, identifying the knowledge segment that can be exploited in developing new products using the tools and knowledge available.

**Figure 15: How an engineer with input from a medical professional can exploit a segment of the medical engineering market**

## 1.9 Future of Additive Manufacturing

The future of AM is in a state of flux. The general public have high expectations, bolstered by sensational articles in the media, that AM is both a brand new technology and the answer to any and all manufacturing problems. In reality, AM has been around for c.30 years [42] and whilst it has its place within manufacturing, it suffers from the limitations and drawbacks discussed previously.

Having said this, AM has the potential to revolutionise the way in which products are developed. AM gives the engineer more control over the geometry and the internal structure of a product when compared to conventional manufacturing [43]. This translates into an accelerated prototyping stage of a particular products life cycle [44]. The following areas may be influenced by AM in the future:

- If the rate at which a part can be fabricated increases, AM could revolutionise the consumer goods market. A product that can be customised and sent to your door the next day would drastically change the way in which companies produce and market their goods, mass manufacture could be succeeded by mass customisation through the use of AM [44, 45].
- The proliferation of AM used in conjunction with conventional machining is likely to take place. AM will enable a company to be more capable to react to changes in a market. Mass production

stifles a company's ability to be agile. However, AM in conjunction with conventional machining could give a company the ability to react to market changes.

- The development of machines to process a greater array of materials is likely to increase the value of the AM market. Machines that can utilise multiple exotic materials at once could strengthen the UK's high value manufacturing industry in the future. The UK must trend towards high value manufacturing as it will not be able to compete with the volume or price of goods manufactured in the developing world.
- Tissue engineering is an area that is currently undergoing rapid growth due to the utilisation of AM. The Bioengineering Research Group in Manchester is a flagship centre for tissue engineering where electrospinning is being utilised to create scaffolding upon which cells can be grown. This type of research will become vitally important as the average age of the population increases because the requirement for innovative medical solutions will follow this trend.
- Material development will become an enabling technology for any future advances in AM as it will drive innovation in the same manner in which it has in conventional manufacturing [12]. It can be hypothesised that there will be an energy efficiency slant applied to future developments due to climate change and energy/waste sanctions imposed upon the manufacturing industry, so the development of materials with lower melting points but with good structural properties might be a future branch of AM material development.

## 2 DEVELOPMENT AND PROTOTYPING OF A BLUNT DISSECTION TOOL

### 2.1 Background

Lancaster University's product development unit (LPDU) received a project brief through its professional network from Mr Ravindra Date who is a consultant surgeon at Royal Preston hospital. The aim of the project was to develop a prototype of a concept surgical tool which could then be used by Mr Date to further its development.

Following on from the initial prototype, utilising additive manufacturing, a PhD project was to be undertaken within the Lancaster University engineering department to advance the concept further.

A specification to design a laparoscopic surgical tool that has the functionality to bluntly dissect the gallbladder of a patient, whose condition is not conducive to laparoscopy by conventional methods was developed within this study. AM was used to create the prototype to fulfil the design brief. With this specification came the need to develop novel mechanisms with which to dissect a gallbladder from surrounding inflamed tissue without the use of a sharp snipping or cutting tool. A sharp tool would be likely to perforate the gallbladder causing bile to leak into a patient's abdominal cavity; this is considered a major complication and would hinder patient recovery [46].

Current laparoscopic gallbladder removal (Cholecystectomy) is carried out with the patient laying face up upon the operating table whilst anaesthetised. Small incisions are made in the abdomen (10-12mm) to insert the laparoscopy tools. With the tools situated in place, the surgeon inflates the abdominal cavity to create a working area. The surgeon then uses a camera to identify the gallbladder [47]. It is at this stage that the operation can progress in one of two directions:

*Scenario one:* The gallbladder is resituated to expose the Calots Triangle, clamped in position and then clipped with a titanium laparoscopic snipping tool allowing for it to be removed [48].

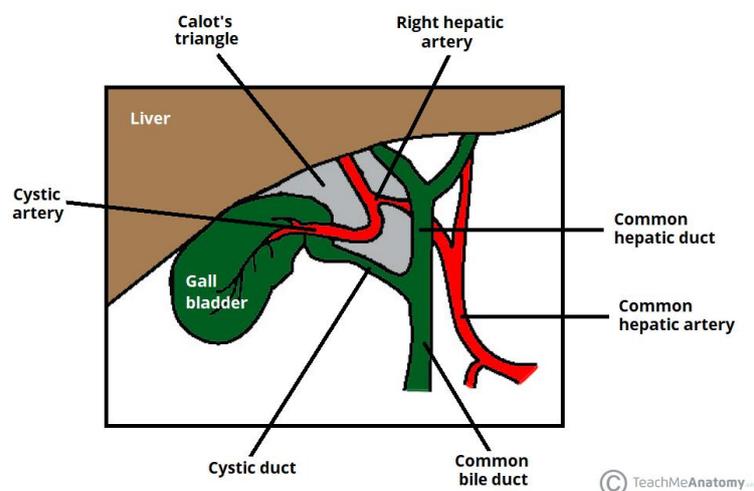

Figure 16: A diagram to illustrate the Calots triangle [49]

*Scenario two:* The gallbladder and surrounding area is deemed to be too inflamed to be removed laparoscopically. In this scenario an open surgery is required. This involves a 100-200mm incision in the abdomen, after which a surgeon manually separates the gallbladder from the surrounding inflamed tissue. To do this the surgeon applies a pressure similar to that required to separate an orange from its loosely bound peel [46]. This type of surgery significantly increases the risk of complications and results in the patient having a longer recovery time. Therefore, a blunt dissection tool is of high value as it would negate the need for this open surgery.

The conversion from laparoscopic to open surgery occurs in approximately one in five cases [48]. For this reason, the need to develop a prototype that would aid in the development of the idea was required by the collaborating NHS surgeon.

The critical mechanical design objectives for the tool were as follows:

- To comprise of two fingers with a curvature to mimic the action of a surgeons fingers;
- To fit within a 12mm diameter envelope;
- To be able to be operated with two hands;
- To be constructed with as few components as possible.

## 2.2 Method of approach

The design of this device was driven by the requirements set out by the NHS collaborator as discussed above. It was agreed that a proof of concept should be prototyped so that the idea could be taken further in the future.

The chosen route to manufacture the prototype was additive manufacturing due to the requirement for the device to be made with as few parts as possible and due to AM allowing for the production of a relatively low cost prototype. As such the design was focussed towards Design for Additive Manufacture (DFAM). This is contrary to conventional DFM criteria where the focus is towards minimising manufacturing complexity. Whilst DFM is a simple principle of reducing complexity to reduce cost, in practice it requires a high degree of manufacturing knowledge and expertise in all aspects of engineering, from materials to the assembly process. Conversely DFAM allows for added geometric complexity at no extra manufacturing cost and removes to a certain extent the requirement for a high level of engineering knowledge [51].

One of the design criteria was for the device to have as few components as possible. SLS was chosen for this reason as it allowed the device to be fabricated without support material and with acceptably tight tolerance enclosed hinges and pivot points.

The rationale behind the use of AM in this case study was to:

- Remove geometric complexity constraints which served to enable design innovation;

- Enable a short lead time from design to manufacture to allow for several iterations if required;
- Facilitate the manufacture of AM joints to reduce the amount of components used.

### 2.3 Dissector Concept 1

Dissector concept 1 consists of two fingers hinged on internal sealed pivots, with each fixture on independent cylinders. The internal pivot points serve three purposes:

- 1) To fulfil the criteria to reduce the number of components of the device;
- 2) To reduce the possibility of a pinch point which could interact with surrounding tissue causing unwanted complications;
- 3) To reduce the number of cavities which would have to be cleaned more thoroughly.

The device's fingers are curved to mimic the curvature of a surgeon's fingers which expedite the blunt dissection during open surgery. The required curvature violates the requirement for the device to fit within a 12mm envelope.

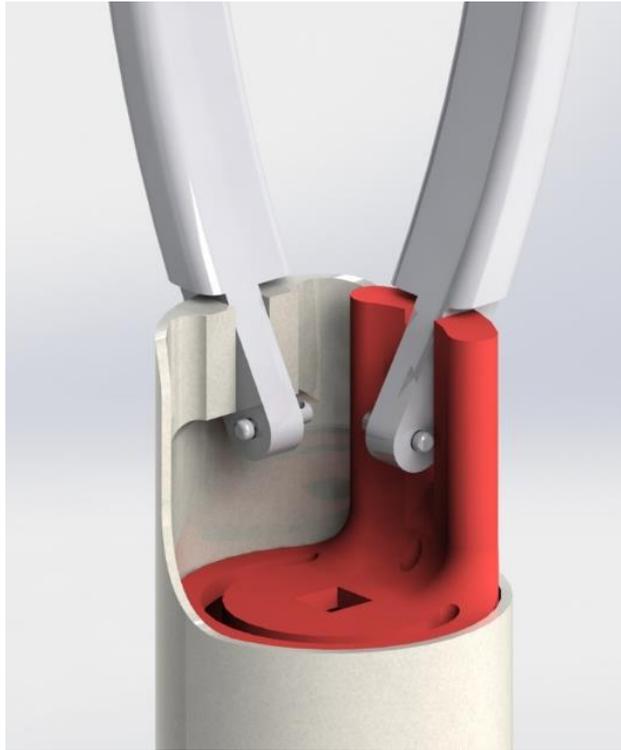

It is a possibility that a composite design of a soft material combined with a skeletal structure composing of a denser material to provide the required rigidity could be investigated in the future. Currently there is not a requirement to pursue this opportunity because the complexity means that it can be deemed out of scope for a proof of concept study.

The pins at the bottom of each finger were fabricated as one in the assembly. They serve as the location point for the actuators which produce the pinching action of the device. The actuators run through the shaft of the device to the conventional scissor action component of a laparoscopy tool.

The most innovative parts of the device are the concentric cylinders which allow the fingers to act as the surgeon's fingers do during an open surgery. This function is the pivotal purpose of the design and requires two hands to operate. The surgeon would hold the stem of the tool (outer cylinder) with their left hand and use this fixed point as the main pivot with which to guide the tool. At the same time the surgeon would rotate the scissor action module which is connected to the inner cylinder, this would allow for a dissecting motion to be achieved.

Figure 17 (A) shows the outer (white) cylinder and the inner (red) cylinder, each are supporting the dissecting fingers by way of an internal hinge.

Figure 17 (B) illustrates the curvature of the fingers and shows the 270 degree extruded cut which allows the actuating wire to transfer unhindered linear motion. The actuation wire was not modelled.

A

B

Figure 17: Detailed view of the blunt dissector mechanism

Figure 18 shows a prototype of the device after being fabricated on the SLS Sinterstation 2000. The SLS process was utilised to manufacture this part from powdered Nylon-12. It was the aim of this prototype to show that a tool that fulfilled the blunt dissecting function could be realised, and this overarching aim was satisfied with this scaled model.

Figure 18 (A) shows the device in the closed position. In this position the fixed dissection finger would support the posterior of the gallbladder prior to the initiation of the dissection.

In Figure 18 (B), the red ring highlights how the inner and outer cylinders interface. This interaction acts as a solid end stop which provides feedback to the user, informing them that they have reached the rotational limit of movement.

Figure 18 (C) displays the tool in the gripping position. Actuation wires would pull on the pins located at the bottom of each dissection finger. This would cause them to pivot about the concealed pivot point within the mounting boss. This functionality is non-critical.

In Figure 18 (D), the image displays the extremes of movement of which the device is capable. The position illustrated would not be required during service but could be utilised during the sterilisation process.

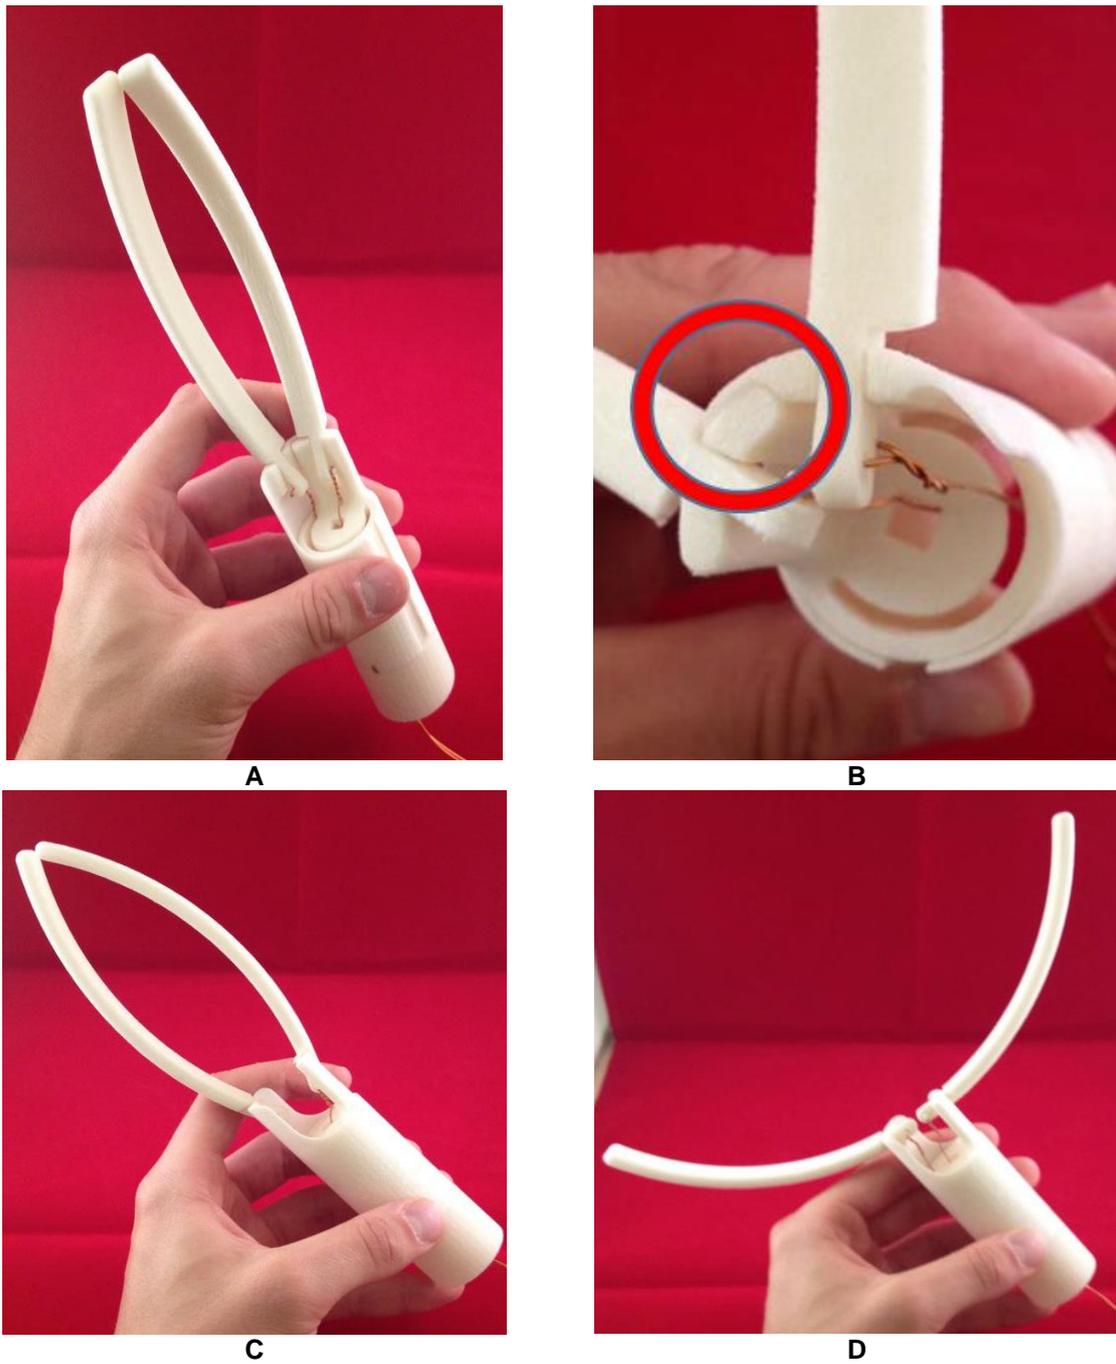

Figure 18: Additive manufactured blunt dissector

## 2.4 Dissector Concept 2

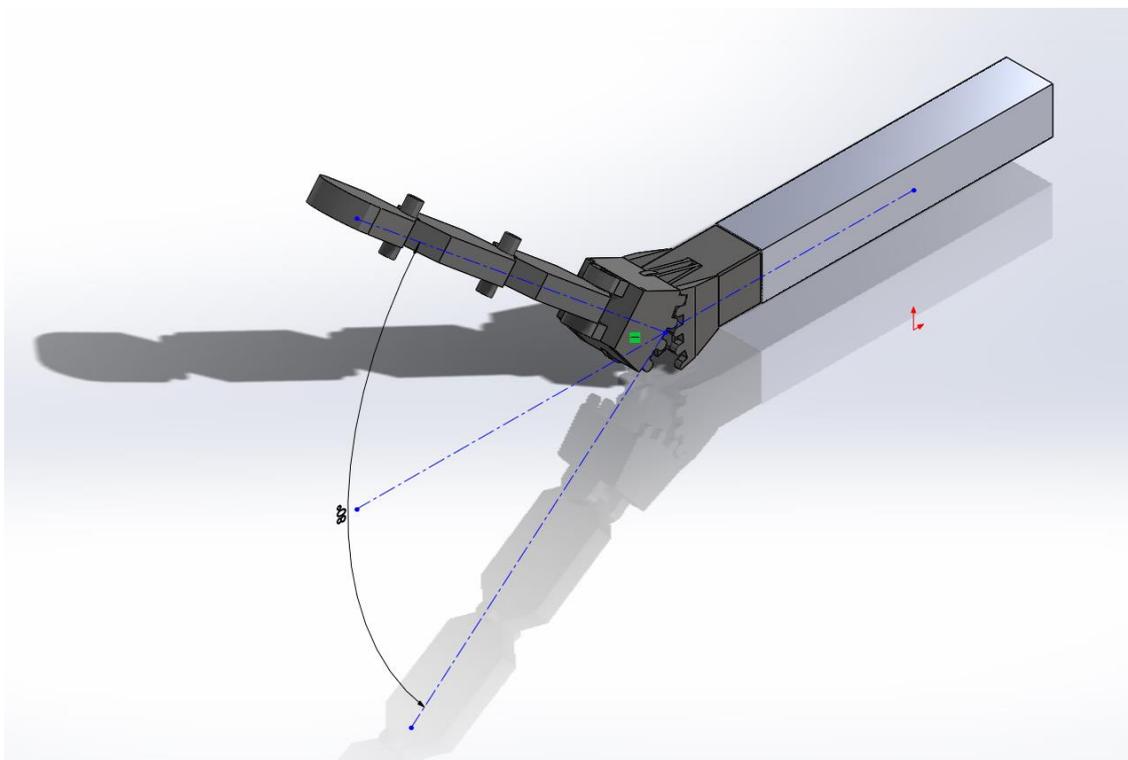

This section aims to illustrate an alternative idea for the blunt dissection of the gallbladder from the surrounding tissue, whereby the dissection finger more accurately represents the form and function of a surgeon's finger. Following a review of the initial prototype with the NHS collaborator, it was decided

that the curvature of the fingers prohibited the insertion of the device through the 12mm diameter hole. To overcome this, it was decided that concept designs for a mechanism which would both achieve the desired curvature whilst retaining the ability to fit through the 12mm diameter hole should be generated.

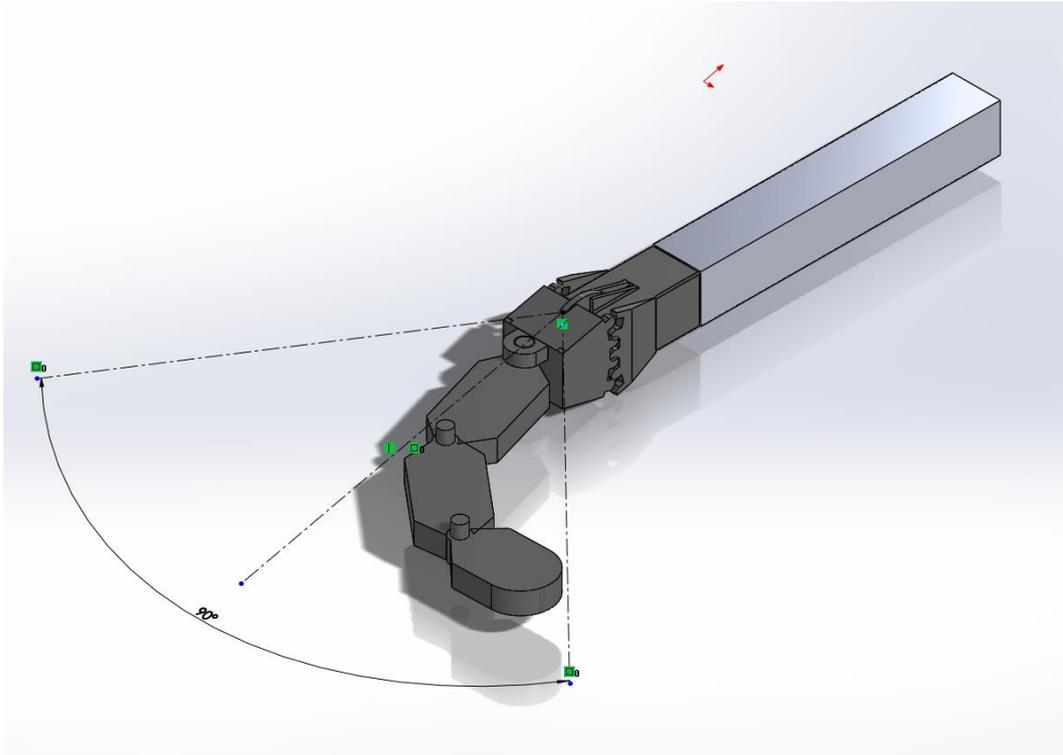

The instrument detailed has five incremental steps of movement in the Y direction but is also capable of free movement in the same plane within the 80° limit (+40° and -40°). The finger also has 90° of movement in the X direction (+45° and -45°). The finger and mechanism could be sheathed in a flexible biocompatible material. The device would be operated in a similar way to current laparoscopic instruments.

Figure 19 (A) shows the limits of movement of the device in Y direction ( $\pm 40^\circ$ ). The pivot point is concealed within the head of the device and the finger is stabilised by the toothed supports.

Figure 19 (B) shows how the device can replicate the movement of a finger. This movement would be actuated with the use of tendon-like actuation wires.

## 2.5 Conclusions

In this study, a prototype was manufactured which successfully demonstrated that:

- a) The principle of a blunt dissection tool could be realised within the limitations of a laparoscopic device.
- b) Additive manufacturing is a suitable means of development for a prototype surgical tool of this kind due to its inherent benefits as discussed previously.

Concept 1 achieved the design brief and demonstrated that a blunt dissector is an achievable concept. The prototype allows for the promise of the idea to be more easily articulated to prospective investor/developers. The main benefit of this device is its potential ability to perform a blunt laparoscopic dissection of the gallbladder; this is currently unachievable with available surgical tools.

Concept 2 endeavoured to explore the possibility of a more complex mechanism which would mimic the movements of a human finger more accurately. Although it achieved its aim as a concept design, it would be complex to manufacture. It is for this reason that concept one is the most appropriate model to carry forward.

The advancement of this device would reduce the number of Cholecystectomies (gallbladder removal surgery) which have to be converted from laparoscopic to open surgery. The benefits of this are multifaceted and far reaching but they can be summarised into: a reduction of overall surgery time, a reduction in post-operative complications.

The scale of the prototype tool was sufficient to convey the idea behind the development of the new tool; however, a prototype which more closely matches the size of the end use tool would give greater credibility to the concept as it progresses.

To scale the device down slight modifications may have to be made, namely the hinge by which the fingers pivot. As the scale decreases the gap between the hinge pin and its pivot body decreases. Because of this it may be appropriate to produce this in two parts and not as an assembly.

The second concept for a blunt dissection finger is advantageous in that it more accurately replicated the action of a human finger but the design requires development as it does not thoroughly detail how the system would be actuated, be it wires or pneumatic etc.

## 2.6 Further work

### 2.6.1 Development of dissection finger

The dissection finger could be optimised further. An attempt at further optimisation was made in concept 2 but was limited by time. A device that mimics the form and function of a surgeon's finger would be an optimum solution for this device. This challenge would require an investigation into the properties of all biocompatible materials; from this, a judgement could be made regarding its feasibility.

### 2.6.2 Material selection

In service, this tool will be in contact with bodily fluids and it is intended that the tool can be sterilised and reused. These two criteria help to define which materials would be suitable. A part-metallic, part-plastic construction would be suitable, particularly stainless steel or titanium as these have a proven track record for in-vivo applications [35]. The plastic fingers of the device are required to allow the device to have a degree of flexibility and structural conformance. The exact material selection is beyond the scope of this report but it is important to point out that if the tool is to be reused it will require a sterilisation pathway.

### 2.6.3 Sterilisation

It is envisaged that the tool would not be autoclaved, which is a process that serves to destroy bacteria and biological pathogens by heating the tool to a high temperature in a pressurised vessel [50]. This would cause plastic parts to fail and so instead a low temperature option must be considered such as the STERRAD sterilisation system, this process utilises hydrogen peroxide gas plasma to sterilise equipment to medical standards [50].

### **3 3D MODELLING CT/MRI SCAN DATA FOR ADDITIVE MANUFACTURE**

#### **3.1 Background**

The brief for the 3D modelling of medical scan data was provided by the author of this study. A large multilocular cyst was discovered when the author was admitted to the acute surgical ward with abdominal pain which they had suffered from intermittently for approximately 13 years. The aim of this study was to use 3D modelling to help with understanding of the condition.

It was acutely apparent to the author that a brief description of the condition by a doctor, coupled with a review of the 2D scan images, was not sufficient to provide a patient with even partial understanding of their condition. A 3D model would provide a patient with greater understanding of geometry and size of a cyst or tumour, the author believes that 3D modelling and possibly even 3D printing of tumour or a large cyst could help with a patients recovery process in many way. For example, in the early stages it could be used by a doctor to provide a patient with a greater understanding of their condition.

3D modelling is becoming more frequently used in the medical industry due it being easily accessible and relatively cost efficient. It is used currently in a variety of applications, the most well-known of which being the production of hearing aids and cosmetic dental devices. The reduction in cost of AM as a technology and the improvement in CAD systems have given rise to a whole host of other applications within the medical industry, from cutting edge research to consumer-ready products, 3D printing is contributing to the advancement of medical treatment.

The following sub-chapters detail how AM is currently being utilised within the medical industry and aim to situate and validate the case study that follows within the current state-of-the-art.

##### **3.1.1 Surgical guides using CT imagery**

A recent study detailed the processes for how a surgical guide to aid mandibular reconstruction surgery could be produced using medical data, CAD software and additive manufacturing [43]. The geometry of the afflicted mandible was captured with a CT scanner which in this case was a 64-channel Philips Healthcare machine. The images taken by this machine were of 1mm slice thickness and of 512 x 512 pixel resolution. The images were saved using the Digital Imaging and Communications in Medicine (DICOM) format [56].

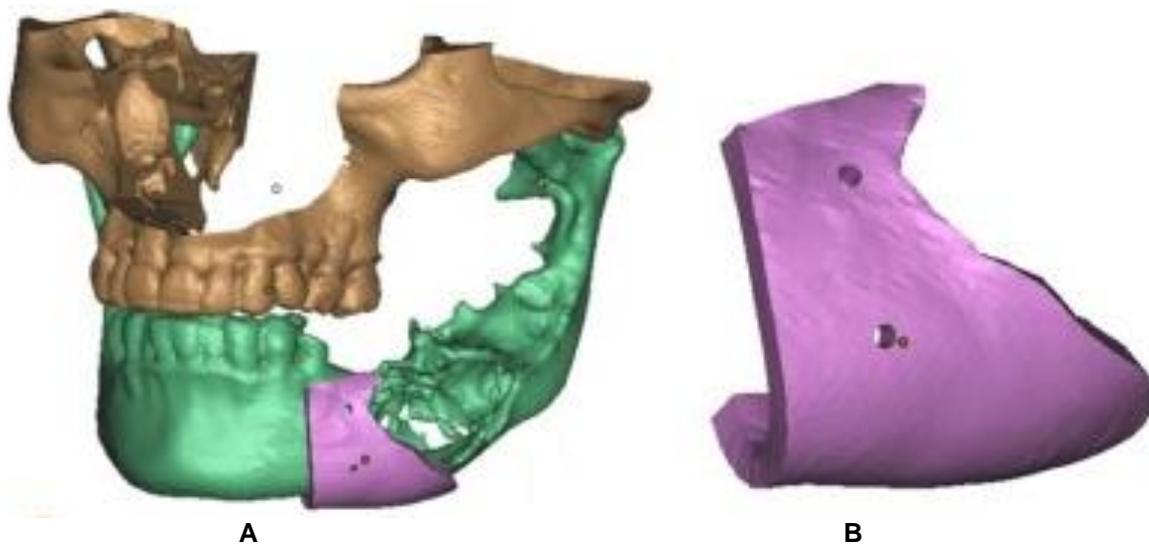

The images were processed into a 3D model using a commercial medical modelling software called Mimics which is a subsidiary software package offered by the company Materialise. In this case, the software produced a model in three steps: firstly, it used the Hounsfield value (HU) setting of cancerous bone to +700 (The Hounsfield unit is a measure of radiodensity which can be applied to CT scan images to separate parts of the human anatomy, for example bone from organ - the HU of distilled water is defined as 0 whereas the HU of air is -1000). Secondly, it defines a 'growing region' which is effectively a threshold to include/exclude areas of a scan that are bordering on the required HU. Finally, a 3D

model calculation combines the layers of the image by effectively performing a lofted boss between the outer edges of the defined area in each layer.

The 3D model was then fabricated using the SLS technique. The SLS machine within this study used biocompatible DuraForm to produce the surgical guide. This is a nylon based plastic. Typically Nylon-6 or Nylon-12 are used in commercial applications. The bed was heated to 70°C before the build was initiated, this preheating allows for a laser to heat each section to just below the melting point of the material. A 15Watt laser power was utilised with a scan speed of 1.25m/s at a layer thickness of 100µm. The layer thickness is defined by the step resolution of the Z axis of the machine.

Figure 21 below shows:

- A) The 3D reconstruction of the afflicted mandible with the surgical guide superimposed in-situ.
- B) An individual isometric view of the surgical guide. The internal curvature of the guide perfectly matches the form of the mandible; it has two holes for two 2mm titanium screws which are designed to hold the guide in place during surgery. Finally, the guide outlines the required cutting path to be performed by the surgeon.

**Figure 21: Additive manufactured surgical guide [56]**

This surgical guide saved 20% operating time and improved the mandible reconstruction in the patient. The guide improves speed and accuracy of the procedure which results in a cost saving and a more repeatable and superior result for the patient.

### 3.2 Method of approach

The following sub-sections detail the method of approach for the modelling of the aforementioned large multilocular abdominal cyst.

### 3.2.1 Medical image acquisition

The patient underwent a MRI scan at the Royal Lancaster Infirmary which resulted in the diagnosis of the aforementioned large cystic mass. The scan was performed using a Siemens 1.5T MRI scanner under the following conditions: Gadovist contrast agent at 7.5 unit volume, GR scanning sequence, 1mm slice thickness, 63Hz imaging frequency, 1.5T magnetic field strength, 580 x 580 pixel band width and a total of 245 images were obtained [57].

An MRI scan works by aligning the protons within the body using a large electromagnet. The scanner then disrupts the position of the protons using radio waves. The realignment of the protons after the radio emitter is turned off produces magnetic fluctuations; these are detected by receivers within the body of the machine. Sophisticated algorithms then build a detailed picture, discerning different tissue types based upon the time it takes each proton to return to its undisturbed position [58].

An individual MRI consists of a 2D flat image taken at a specified depth within the body, which can then be combined with other images at different depths to form what is known as an MRI scan. This construction is very similar to that of 3D printed files so it lends itself to being reproduced in 3D using additive manufacturing.

Figure 22 (A) is an image obtained from a CT scan; it shows a large multiloculated mass engulfing almost the entirety of the bottom half of the abdominal cavity. The large/small intestines and appendix have been displaced into the upper left of the patient's abdominal cavity. The mass has a diameter of approximately 300mm and an average depth of approximately 150mm.

Figure 22 (B) illustrates the human anatomy and details the internal organs. It can be seen that the small intestine, large intestine and appendix are located within the lower half of the abdominal cavity.

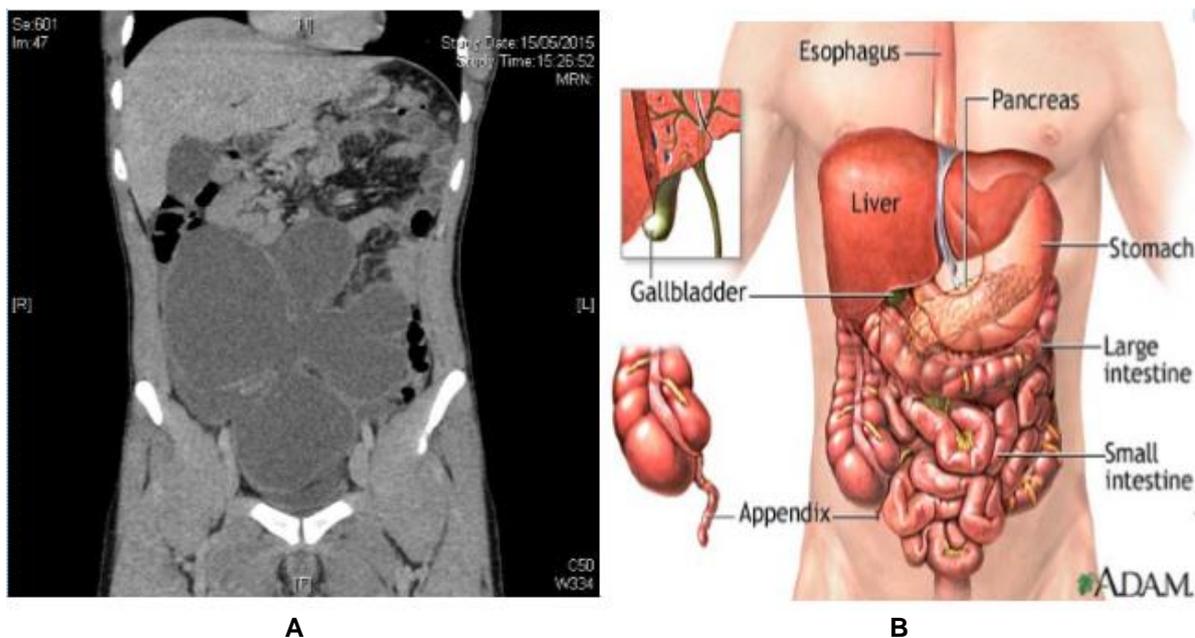

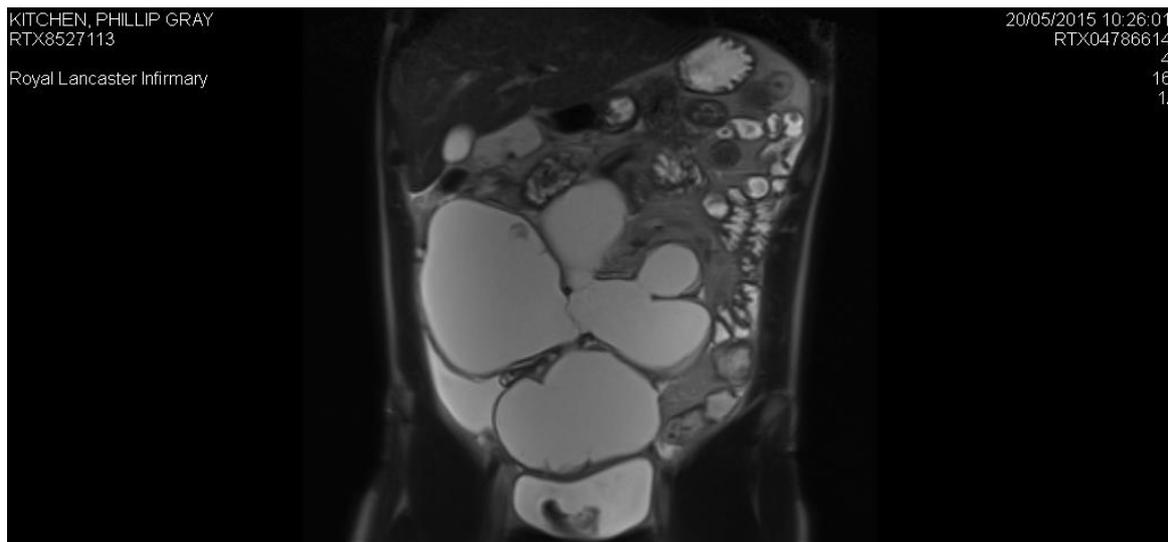

Figure 22: Extent of the cyst within the patient

Figure 23 is a high resolution image obtained from the MRI scan. From this, it can be seen that the mass has an irregular shape. Three of the four chambers are shown to be connected in this image; the fourth (lower) chamber can be seen to be connected in subsequent MRI slices. The consistent hue of the interior of the mass indicates that mass is filled with fluid. Further to this, the bright area, approximately where the appendix should be, is an area of abnormal fluid collection. The patient's blood tests revealed high inflammatory markers which could be responsible for this. However, the large mass was independent to the symptoms with which the patient was admitted to the acute surgical ward.

**Figure 23: High resolution image obtained from MRI data**

### 3.2.2 Conversion into a 3D model

#### 3.2.2.1 *Slicer 4.5*

3D slicer is open-source software [59] which allows the viewing of DICOM medical images. It has the functionality through skilled manipulation to compile MRI or CT images into a 3D model which can be exported in a variety of formats (including stl). The software has limitations when compared to its commercial counterparts (e.g. Mimics-Materialise) in that it allows for limited manipulation of the 3D model. Filters can be applied but they are 'optimised' for the selection of bones and are not suited to the segmentation of relatively similar materials (in physical composition) such as organs.

### 3.2.2.1.1 Loading the data

Figure 24 shows the layout of the program with a set of MRI images in place. To import the DICOM images, 3D slicer has a feature where the images can be dragged and dropped into the 'conventional view' area of the user interface (highlighted by the red box). All data sets were imported at the same time from the master folder in this way.

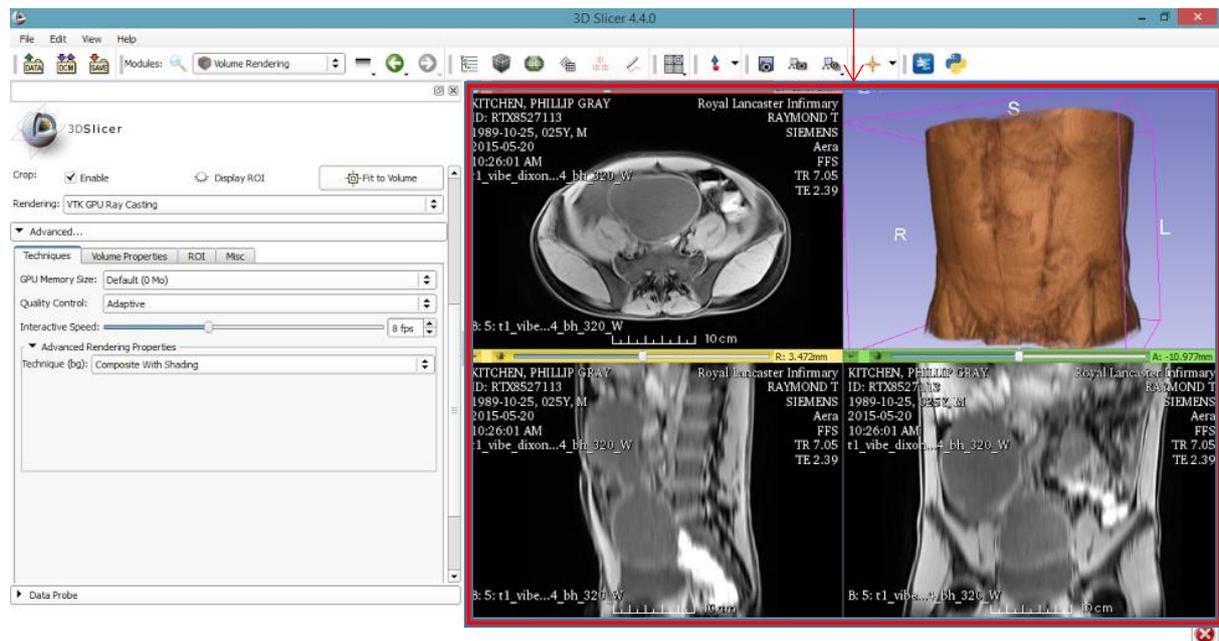

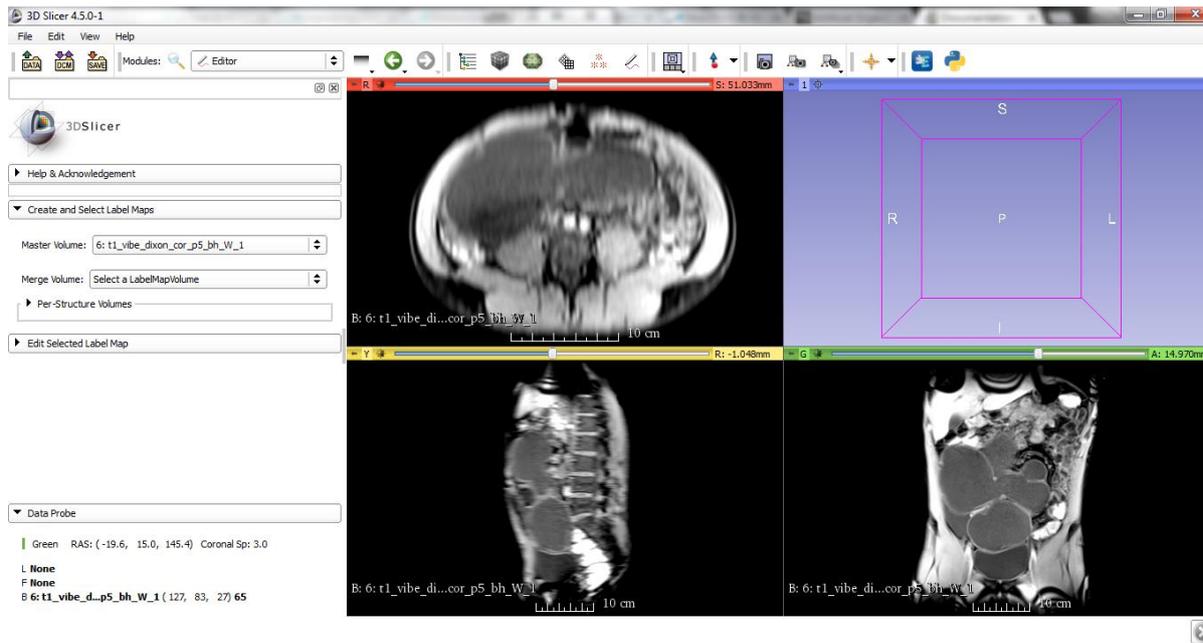

Figure 24: User interface of the modelling software

### 3.2.2.1.2 Selecting the most appropriate data set

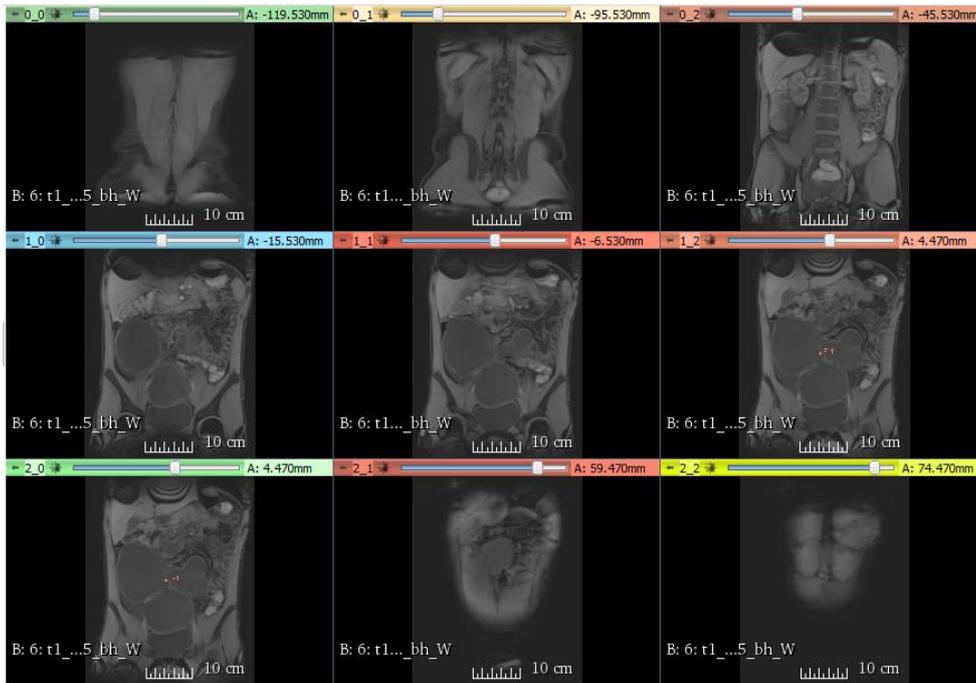

Within the MRI DICOM files that were obtained from Royal Lancaster Infirmary, there were 12 sets of data, each of which represented a full scan of the patient's body. Half of the data sets were pre-contrast injection (which is used to highlight certain areas of the body), half post-contrast injection. It was observed that the dataset in which there was the greatest contrast between the cyst and its surrounding organs/tissues would be the most appropriate data set because the 3D modelling relies on the setting of a threshold to select similar pixels. Data set - 6: t1\_vibe\_dixon\_cor\_p5\_bh\_W\_1 was chosen for this reason (Figure 25).

**Figure 25: Location of the appropriate data set**

### 3.2.2.1.3 Estimating the dimensions of the cyst

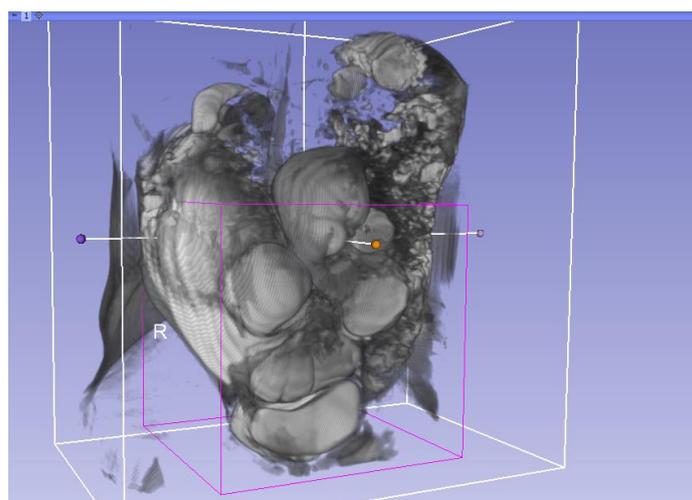

The data set 6: t1\_vibe\_dixon\_cor\_p5\_bh\_W\_1 was also deemed the most appropriate to gather approximate measurements of the cyst. The depth of the cyst can be approximated from the sliding scale on each segmentation image. It can be seen that the cyst's anterior region begins at +66.47mm and the posterior region ends at -45.53. This means the maximum depth of the cyst is approximately 112mm. The maximum width can be approximated from the scale provided at the bottom of each image; it is approximately 210mm across at its widest point (Figure 26).

**Figure 26: Data used to estimate the approximate dimensions of the cyst**

### 3.2.2.1.4 Volume Rendering

This feature allows the viewing of the MRI scan data in 3D (Figure 27). This is not a model that can be exported as a stl file, it is merely a feature that allows for easier cropping of the image. The filter that highlighted the cysts most precisely was the filter specifically thresholded and coloured to visualise coronary arteries (CT-Coronary-Arteries).

**Figure 27: Visualisation of the cyst**

### 3.2.2.1.5 Cropping the area of interest

The volume rendering helps to inform the region of interest about which the cropping is to be performed. The region of interest is cropped to create a sub-volume with which to create a 3D model in the later stages.

In the upper right image of the conventional view in Figure 28, it can be seen that the cyst has been segmented as much as possible from the surrounding anatomy. The bladder, which has a similar threshold range has been cropped out. This is important as it would be difficult to segment them at a later stage.

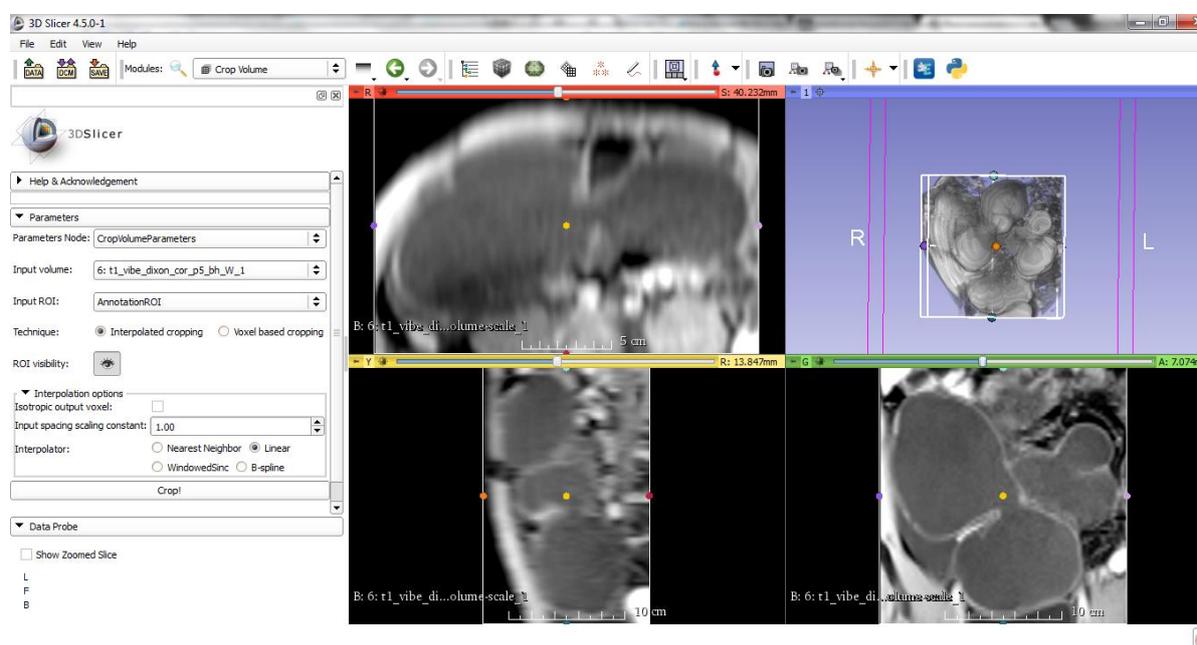

Figure 28: Cropped plot of the cyst data

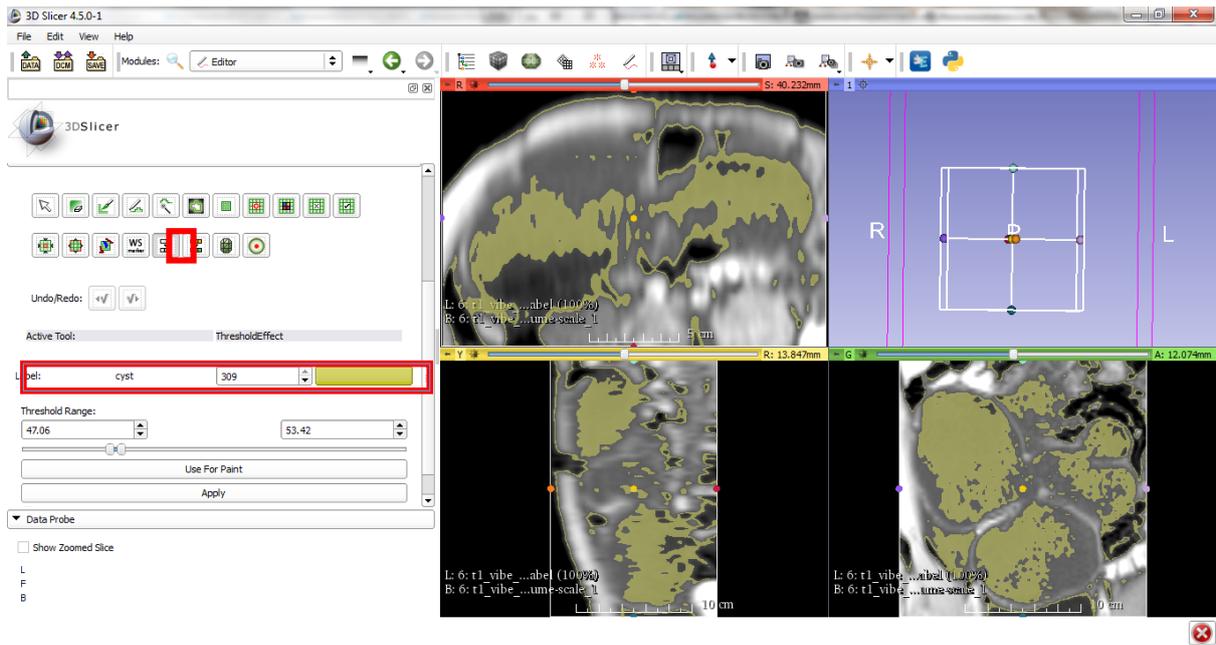

### 3.2.2.1.6 Creating a 3D volume

A label map was created in the editor module in which the cyst was segmented out as much as possible from its surrounding tissues/organs. A label map is a scalar volume in which each volume is assigned a number. Zero is automatically defined as the background (anything not highlighted) and the cyst is recorded as '309', this is just a pre-set number, it holds no special information. The numbering system would be useful if more than one organ/bone/tissue was to be modelled.

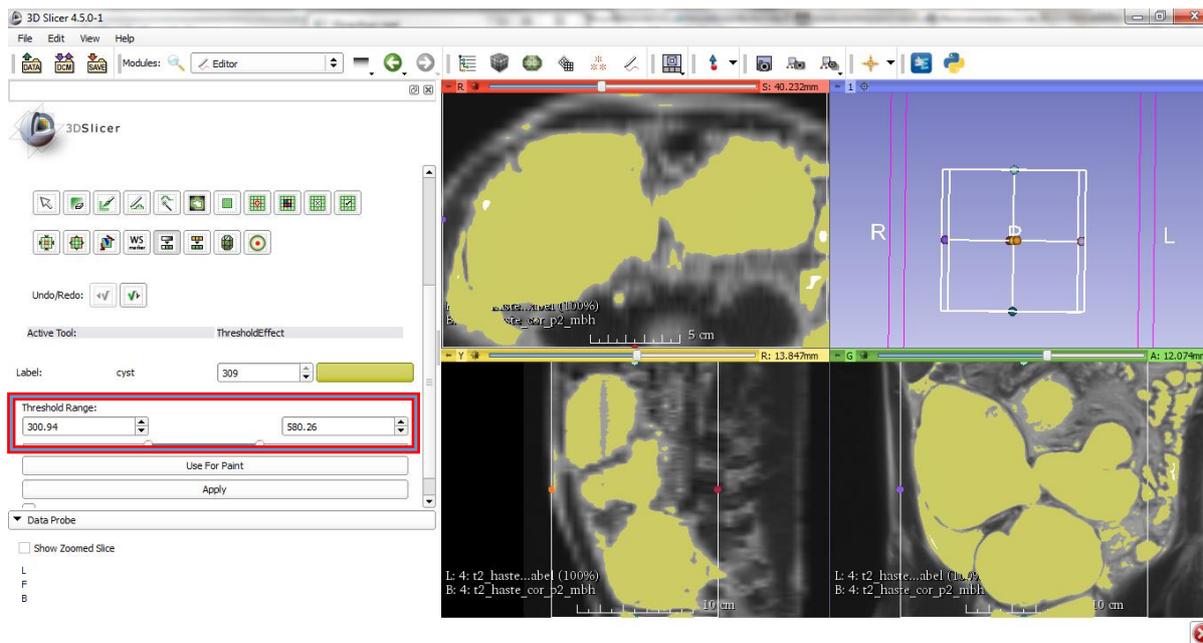

Figure 29 (A) shows the initial set up of the threshold feature. It can be seen that Cyst 309 is selected and that the threshold slider scale does not fully match the volume of the cyst.

Figure 29 (B) shows that with the threshold set to between 300-580, the entirety of the cyst's volume is highlighted throughout each cross-section. The limitation of the software is that it is not sensitive enough to differentiate the cyst completely from its surrounding tissues. The software does not provide an easy solution to model the cyst but it does allow for a representative 3D model to be created which can be edited in separate software such as MeshLab as a refinement stage.

This Scalar volume was then saved as a stl file to be imported to a secondary software package for refinement.

A

B

Figure 29: Process of modelling the cyst

### 3.2.2.1.7 Model refinement

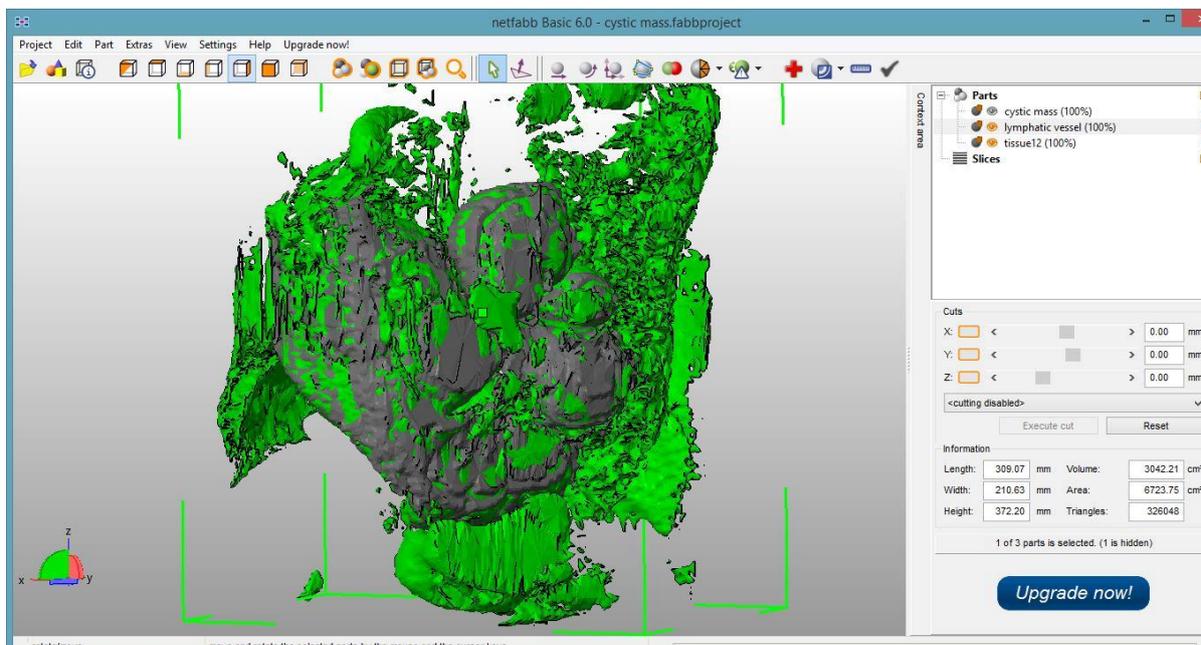

Netfabb (software used to view, repair and edit stl files [60]) was used to improve the stl file and to remove the bulk of the excess tissue which remained after the processing in Slicer 4.5. The file was saved at different stages to detail the progress and to protect against sudden computer failures provoked by the act of performing the cleaning process. Removing vertices and faces from a high poly model is a RAM intensive process, so it was prudent to perform it in stages.

The following images show three stages in the clean-up of the file, it can be seen that a large proportion of the excess data has been removed from the model.

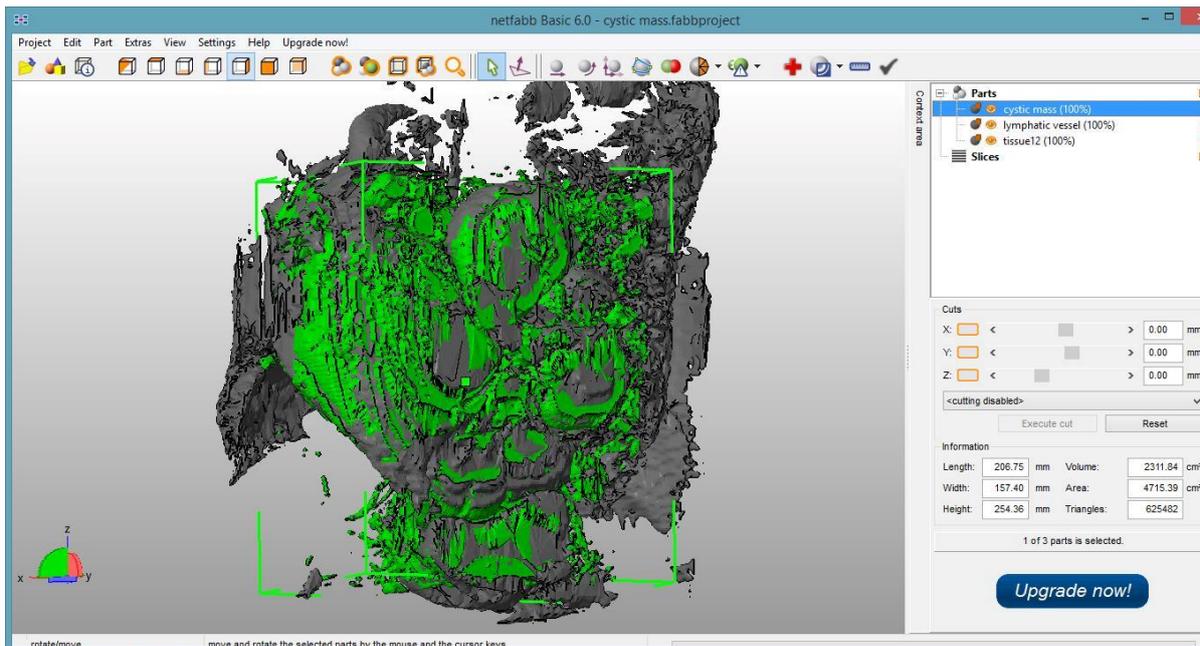

Figure 30 (A) shows the most unrefined stage of the model which has been superimposed onto a later improved stage. It can be seen that the Slicer 4.5 method of creating a model is not very sensitive to the anatomical differences of cysts and other organs in the abdominal cavity.

Figure 30 (B) shows an intermediate stage of refinement which was saved to prevent data loss in the event of the program crashing as this is a common occurrence within this operation due to its RAM intensive procedure.

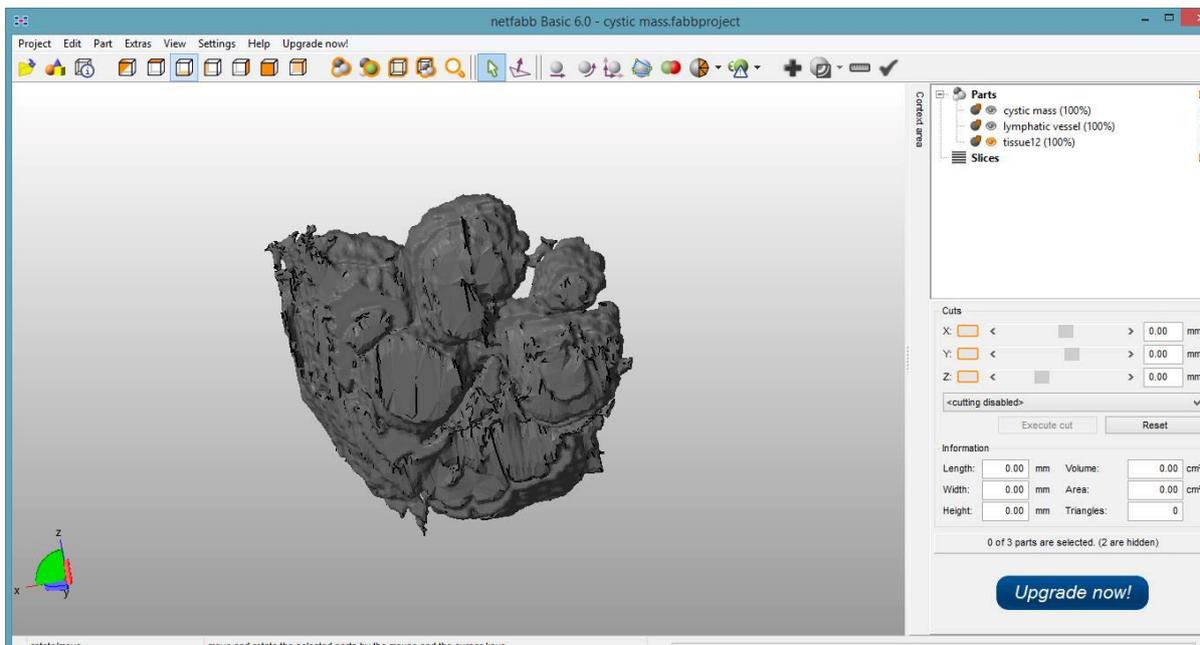

Figure 30 (C) shows the final stage of model refinement, indicating that the cystic mass is free from the majority of its surrounding tissue.

A

B

C

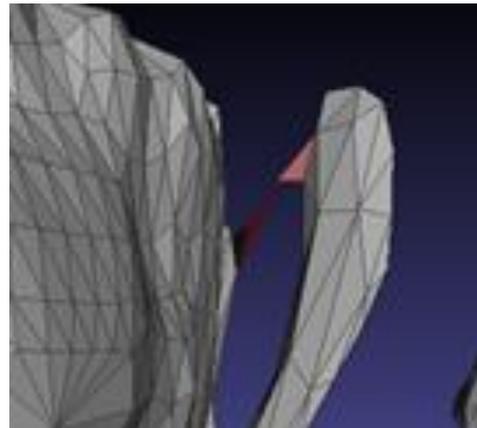

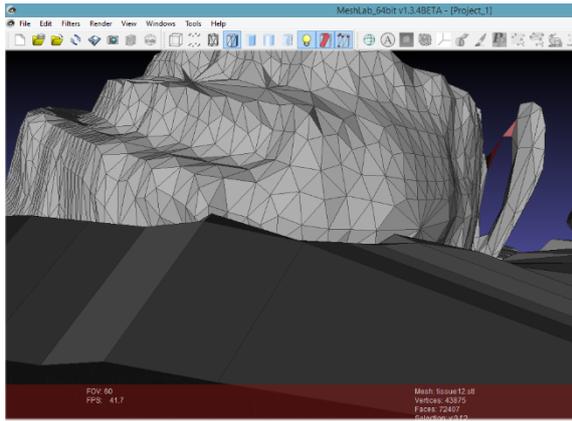

Figure 30: Manipulation of the cyst stl

### 3.2.2.1.8 Further model refinement

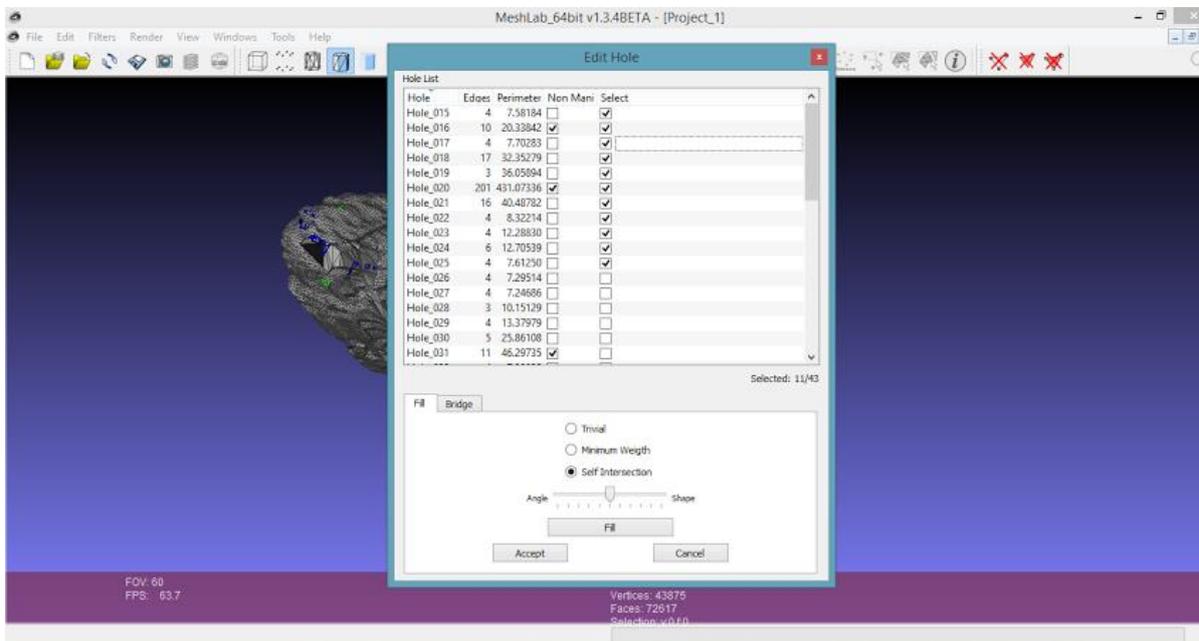

MeshLab, a software package which offers tools to edit, heal and inspect large stl files [61]. Offered the opportunity to further refine the model. Figure 31 (A) shows how the highlight and deletion of faces enabled the model to more accurately represent the surface of the cyst. There were many erroneous

structures which had to be edited. At this stage the model had 72,407 faces which were scanned for abnormalities.

Figure 31 (B) shows that the deletion of these faces created holes in the mesh, which were filled using the 'fill hole' function. The fill hole function bridges the gaps in a mesh, it is important for this model to be 'water tight' – have no holes in the mesh so that it is representative of the mass and so that it could be 3D printed.

A

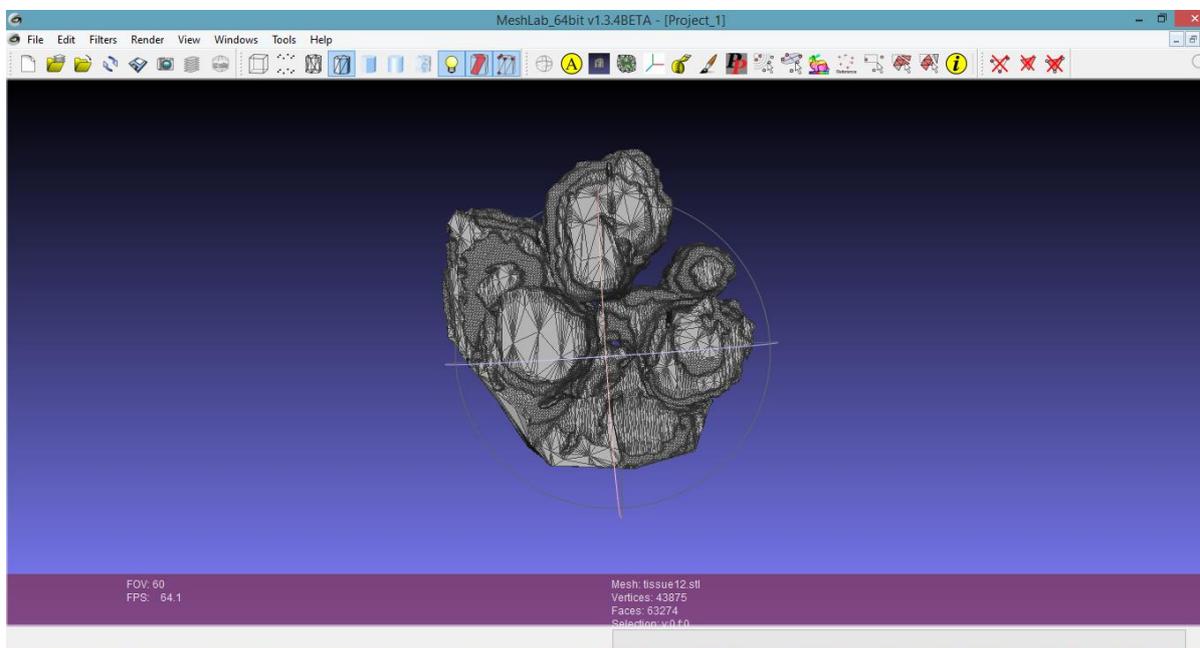

B

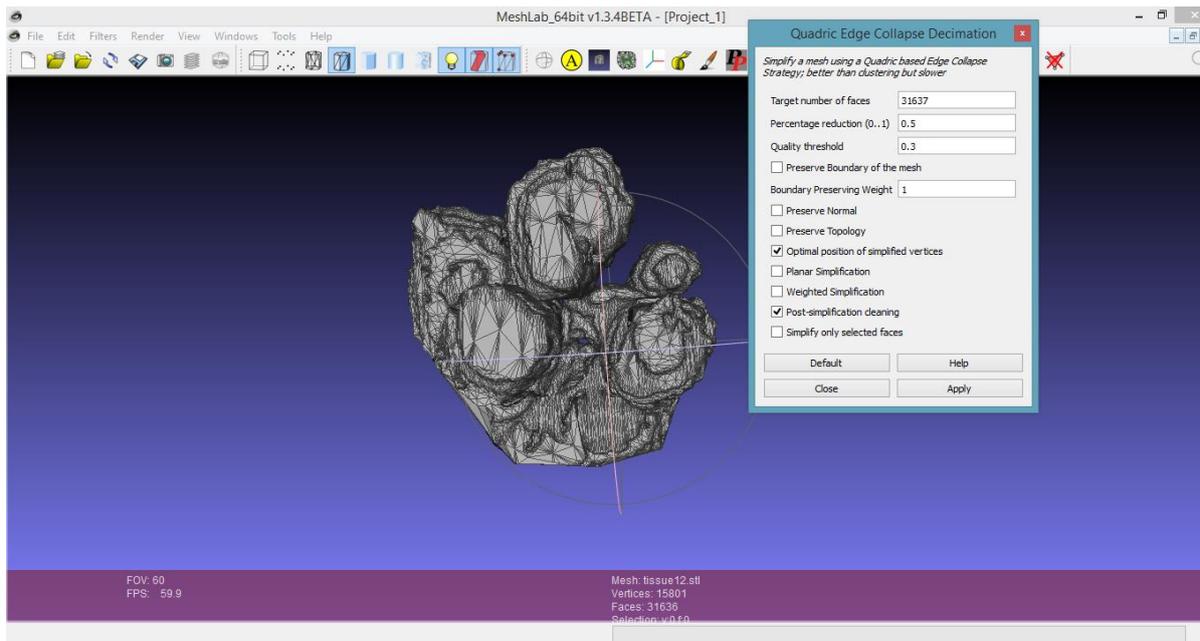

Figure 31: Part of the stl manipulation process

### 3.2.2.1.9 Model simplification

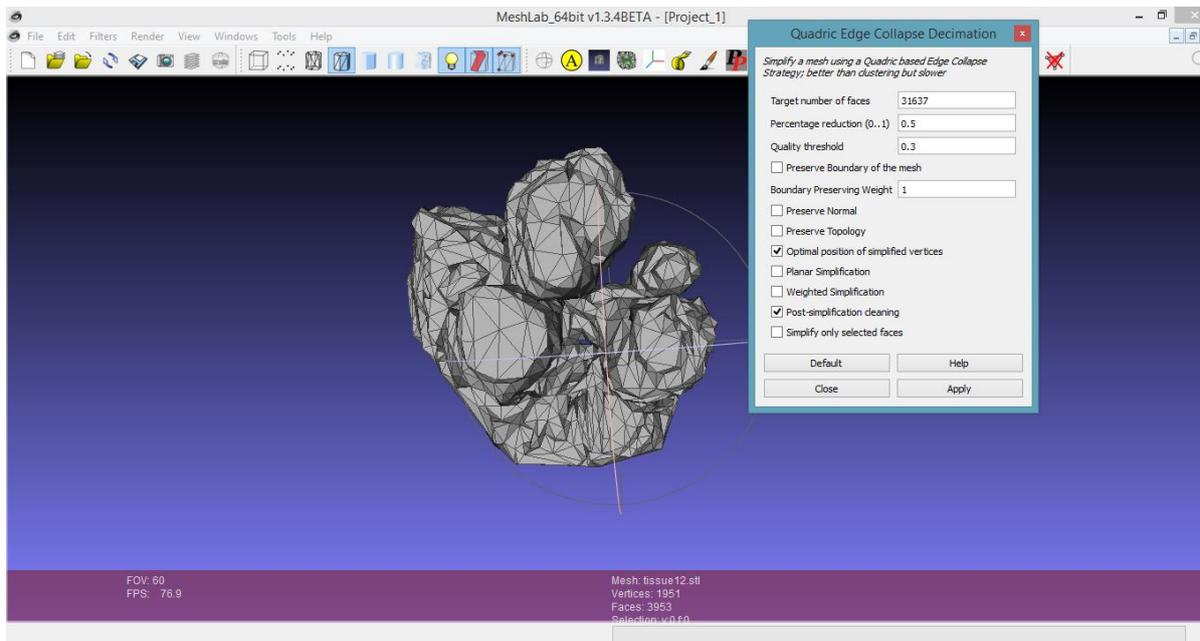

After the model was improved, a simplification process was carried out with a view to removing the number of faces and therefore making the model easier to process by the AM machine. A model of this size would not benefit geometrically in any discernible way from being so high poly (high polygon count mesh which is fine resolution), so a reduction will reduce the print time and processing time with no detrimental effect to its quality. This was achieved using the Quadric Edge Collapse Decimation function; this facilitated the reduction from 74,000 to 4000 faces (Figure 32 A-C). Quadric Edge Collapse Decimation is a common method of mesh simplification [62] and is a built in function within MeshLab. The boundary of the mesh was preserved to maintain the external geometry of the model.

A

B

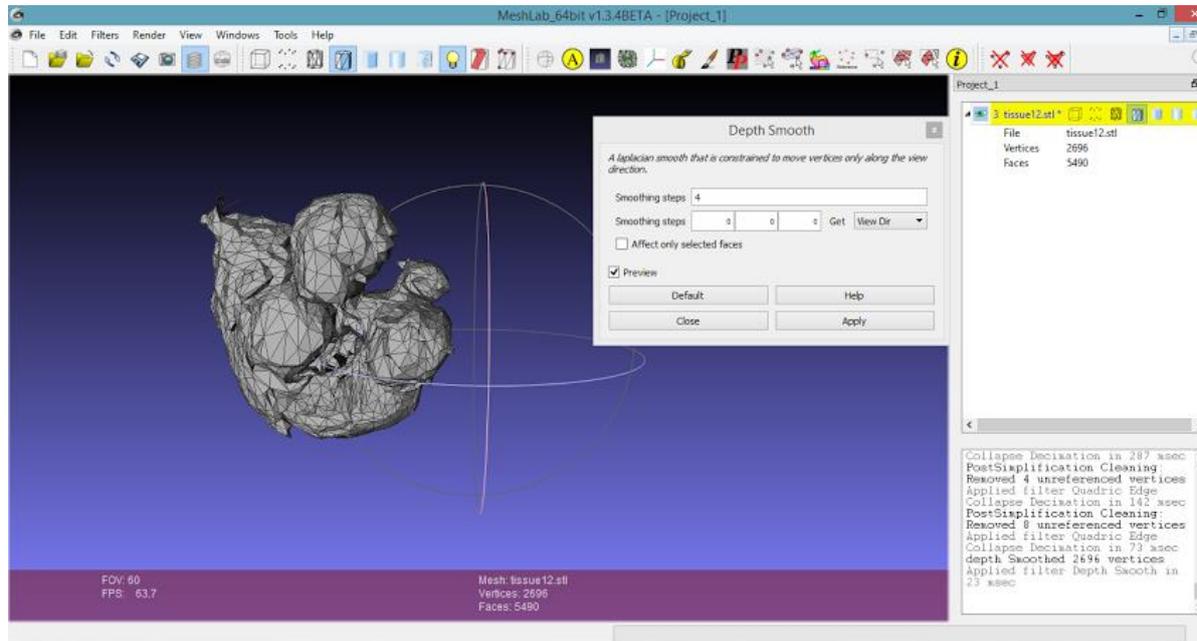

C

Figure 32: Simplification of the cystic mass stl

### 3.2.2.1.10 Smoothing

The reduction in faces detailed above resulted in the model becoming too angular. To rectify this, it was possible to utilise the 'Depth Smooth' function within MeshLab. This increased the number of faces from 4000 to 5500, but resulted in a more representative model (Figure 33). Simplifying the model to 4000

and then adding detail to the mesh to 5500 faces allowed the model to become smoother/ less angular and more true to life. The result of this can be seen in the figure below.

**Figure 33: Smoothing of the cystic mass stl**

### 3.3 Conclusions

The model produced using Slicer 4.5 was not as representative of the cyst as it was first envisaged. The software was not sensitive enough to fully differentiate between the cyst and its surrounding tissue, as later discussed software packages exist which may be more suited to the task. Due to this lack of sensitivity an extended amount of time was required to improve and simplify the model in secondary stl manipulation software.

The lack of sensitivity lead to the model produced not being as useful to the patient. A fully representative model would provide the patient with a greater understanding of their condition. As discussed earlier in this study, a patient cannot hope to garner a full picture of their condition from observing an MRI scan as they don't have the training to interpret it. A 3D model would give the patient a clearer understanding.

In conclusion, a more sophisticated software package would be an appropriate step forward in the development of this study. In particular a piece of commercial software called Mimics InPrint from Materialise facilitates the generation of 3D models from scan data but a seat of this software costs in excess of £20k so it was deemed to be beyond the scope of this thesis to investigate this software.

### 3.4 Further Work

The modelling of the cyst could be performed in commercial medical image specific software such as Mimics by Materialise. This software could have provided a more representative model, however access was not granted to a free version of this software and the cost of purchasing a commercial licence would have exceeded the budget of the project.

However, the modelling could be performed in SolidWorks which is a powerful 3D CAD software already available to the author. The process of producing a 3D representation of the cyst would consist of four main steps:

1. Create a plane for each image along one axis;
2. Trace the outline of the cyst in each image using the spline tool;
3. Perform a lofted boss to follow the contour of each slice;
4. Export the model as an stl file.

This method could produce a more representative model which could be improved and simplified more easily as a secondary stl file using a manipulation software package, such as MeshLab.

## **4 DEVELOPMENT AND PROTOTYPING OF A NOVEL FLUID-MIXING DEVICE WITH POTENTIAL CLINICAL APPLICATIONS**

### 4.1 Background

A brief was presented to the author to simulate and manufacture a prototype novel fluid mixing device. This prototype is to be investigated as a potential medical/biomedical device, in line with current trends over the past decades towards micro mixing devices being applied in the biomedical industry, particularly for disease diagnosis and genetic analysis. There is a drive towards (1) increasing efficiency - resulting in less biological material requirements (2) less material requirement – resulting in lower manufacturing cost.[63]

Additive manufacturing was selected for this study as it would facilitate the device to be manufactured in one piece, thereby reducing construction cost and computational fluid dynamics (CFD) was utilised to simulate the most efficient mixing angle so that the device could mix fluids in the most efficient way.

The purpose of this study was to develop, 3D model and prototype a novel method of mixing fluids utilising the creation of a vortex within a chamber. To achieve this, the study first details the state-of-the-art with regards to how current micromixers function. This is followed by a description of the process which was undertaken to develop and simulate the effectiveness of a novel mixing device. During initial assessment of the potential design and function of the device it was clear that the complex geometry would mean that the device could only be manufactured through additive manufacturing methods.

Micromixing devices are loosely defined as mixers which contain channels from a few millimetres in diameter down to nanometres. Within these parameters normal mixing mechanisms such as convection do not apply, the major mixing mechanism in micro-mixing applications is diffusion [66].

It is necessary to establish why this is the case. This can be established with a description of how laminar flow affects mixing, followed by proof to show that laminar flow is likely in small diameter pipes. The Reynolds number is a dimensionless value which aids in the prediction of how laminar a fluid will be, given certain parameters. Equation 2 below illustrates why this behaviour occurs in channels of small diameters.

$$Re = \frac{DU}{\nu} \quad (\text{Eq 2})$$

Where  $U$  is defined as the flow velocity,  $D$  is the diameter of the pipe and  $\nu$  is the kinematic viscosity of the fluid. As mentioned above, micro-mixing applications utilise pipes and channels which are of the order of 2-3mm or less so it can be deduced that a small number in the top half of the equation will result in a low Reynolds Number. This can be assumed with the assumption that  $U$  is also relatively small. The lower the  $Re$  number, the more laminar the flow [67].

A laminar flow is not conducive to mixing. Laminar flow has the following characteristics all of which are not ideal for the mixing of fluids and all of which are present in small diameter pipes of less than 2mm: no lateral mixing, no cross currents or eddy currents [67].

It is turbulent flow and convection which aids in the mixing of fluids. In the absence of these, diffusion is the main mixing mechanism. Diffusion is a relatively slow process defined in micro-channels by Equation 3:

$$Pe = \frac{DU}{D_{mol}} \quad (\text{Eq 3})$$

Where  $U$  is defined as the flow velocity,  $D$  is the diameter of the pipe and  $D_{mol}$  is the molecular diffusivity of the fluid.  $Pe$  is the Peclet number which is equal to the product of the Schmidt Number (viscous diffusion rate / mass diffusion rate) and the Reynolds Number. So it can be seen that the rate of diffusion is defined and constrained by the diameter of the channel within which it flows [66].

The mixing of fluids in the medical and pharmaceutical industry is a challenge of principle importance. The rapid mixing over short distances is essential for many industries, it is utilised within cell activation processes for medical research, drug delivery systems in hospitals and to facilitate the chemical reaction within lab-on-chip platforms for chemical research [66].

Micromixers can be subcategorised into two categories, passive and active. Passive devices require no external impetus, instead they utilise diffusion or varying degrees of chaotic advection through the use of a staged internal geometry which forces the liquid to take turbulent paths. Contrary to this, active micromixers utilise external forces to agitate the flow thus creating more conducive mixing conditions. Some examples of external impetuses applied to active micromixers are: pressure, magnetism, vibration, acoustics and temperature. Because of the added complexity of active micromixers the fabrication process is more complex which results in a much higher cost to manufacture. Active micromixers also cost more to operate due to the associated energy costs or running an external agitator, whereas, passive micromixers require no extra energy. The choice is a compromise between running/manufacturing costs versus functionality [67]. In this study, a novel passive micromixer is designed and the mixing efficiency is simulated to optimise the design.

## 4.2 Passive micromixers

Passive micromixers have two main mechanisms for mixing: diffusion and chaotic advection. Micromixing devices aim to decrease the diffusion path and increase the total area in which the two fluids are in contact. If the above aims are achieved, it can result in a shortened mixing time/distance which is desirable for most applications.

#### 4.2.1 Parallel lamination

Parallel lamination micromixers split the two fluids into two streams and direct them in line with each other thereby increasing the distance at which the fluids are in contact with one another. This means that there is a greater overall surface area contact between the two streams resulting in greater mixing.

This method utilises molecular diffusion as its main mixing mechanism, this means that long channels are needed and it is advantageous to input the fluids at low velocity to achieve a low Reynolds Number which will extend the mixing length.

#### 4.2.2 Injection

Injection micromixers can offer a significant improvement in mixing efficiency over parallel and serial lamination. The mixer splits the fluid to mix into separate channels and injects them into the main base fluid, this creates micro-plumes which creates turbulent flow and increases the area of contact between the two fluids.

#### 4.2.3 Chaotic advection

Advection is a principle method to increase the rate of mixing within micromixing devices which exhibit a low Reynolds number. The increased mixing rate is achieved through the creation of complex geometries within the fluidic channel. Furthermore, these complex geometries are commonplace in macromixing static mixing devices. Figure 34 shows examples of the chaotic advection technique utilised within macromixing nozzles. The nozzles pictured are used to mix a two-part adhesive. They are used within an automated adhesive application cell at the Sheffield AMRC. The nozzles are mounted on an end effector of a robotic arm and the two-part adhesive is extruded through, using large stepper motors which index in the negative Z direction through reservoirs of adhesive and promoter.

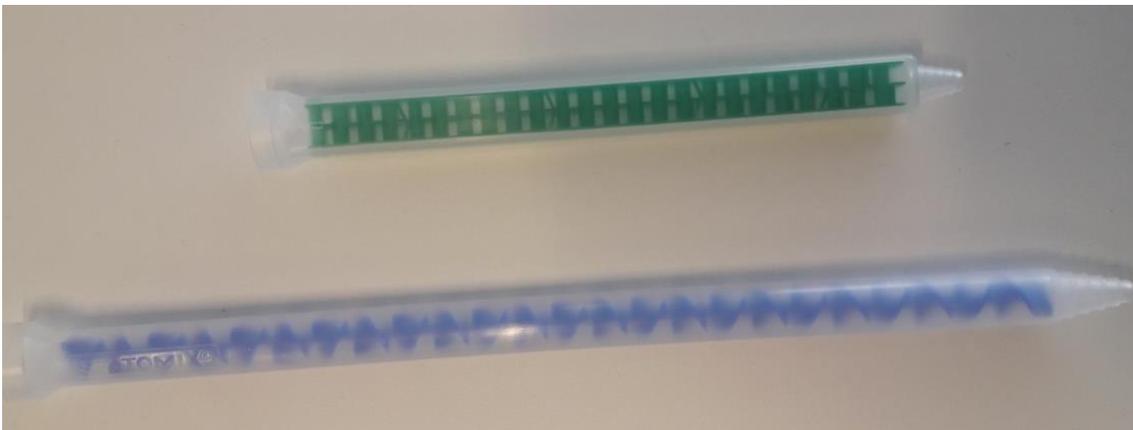

Figure 34: Examples of mixing nozzles

The principle of chaotic advection is to agitate the flow by modifying the channel diameter, breaking and inhibiting the flow. Physically this is achieved by adding structures within the channel which act as obstacles to the flow.

#### 4.2.4 Active micromixers

Active micromixers utilise a vast array of mechanisms to achieve an increased rate of mixing. External equipment which ranges in approach from magnetism to acoustics, facilitate this rate increase.

##### 4.2.4.1 *Pressure field disturbance*

As an early development in micromixing technology, this approach was manufactured using silicon, which has become common place for active micromixers.

Pressure disturbances can be applied in a variety of methods however a common and reliable method is achieved by pulsing the velocity of the fluid. In these systems the mixing efficiency is related to the pulsing frequency.

##### 4.2.4.2 *Electrohydrodynamic disturbance*

The structure of electrohydrodynamic disturbance mixing devices is similar to that of pressure field disturbance devices, however, the mixing channel can be upwards of 30mm long. Titanium wires are placed at regular intervals perpendicular to the flow of the fluid. In these systems the mixing efficiency is related to the electric current and signal frequency.

##### 4.2.4.3 *Thermal disturbance*

The rate of diffusion between fluids is closely linked to temperature; the greater the temperature of a fluid, the more active it becomes on an atomic level which increases diffusion. Methods which attempt to achieve greater mixing efficiency using thermal disturbance have included: introducing a temperature gradient across a standard parallel mixing channel and the creation of a thermal bubble within a channel to agitate the flow.

#### 4.2.4.4 Acoustic disturbance

An acoustic disturbance micromixing device utilises acoustic agitators to achieve an increased rate of mixing. One challenge with the acoustic disturbance technique is that the act of agitating in this manner increases the temperature of the fluid. This would be an undesirable side effect if the fluids characteristics were altered detrimentally by the temperature change. For this reason, the acoustic disturbance technique is not recommended for some biological fluid applications. In acoustic systems the mixing efficiency is related to frequency of the sound waves [67, 68]

#### 4.2.5 Method of approach

##### 4.2.5.1 Current manufacturing methods

The current manufacturing techniques used for manufacture of micromixers are polymeric micromachining (plastics laser micromachining) and silicon micromachining.

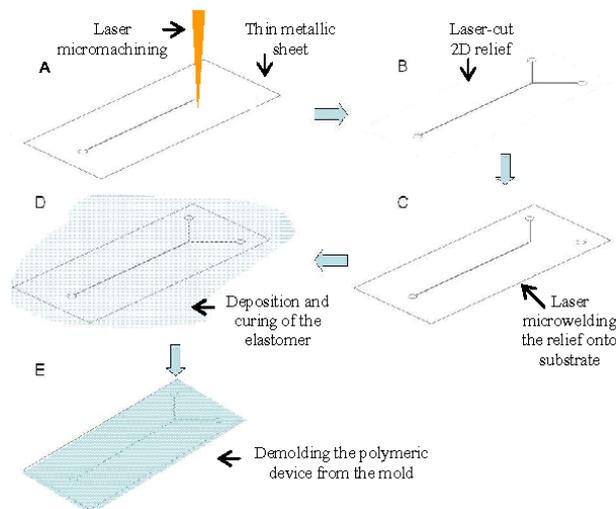

Figure 35: Illustration of polymeric micromachining [64]

In the infancy of micromixing development, silicon was the most common material choice, with the channels either wet or dry etched. A clear acrylic or glass cover would then be bonded over the etched channels to provide a seal and visibility. Further to this, a passive micromixer can be manufactured entirely of glass if the application requires a non-electrically conductive device.

Active micromixers are almost solely manufactured from silicon. There are compromises to this in that they are expensive to manufacture, due to the requirement for tight controls of the environmental conditions. A further compromise is that silicon is not compatible with some chemical applications.

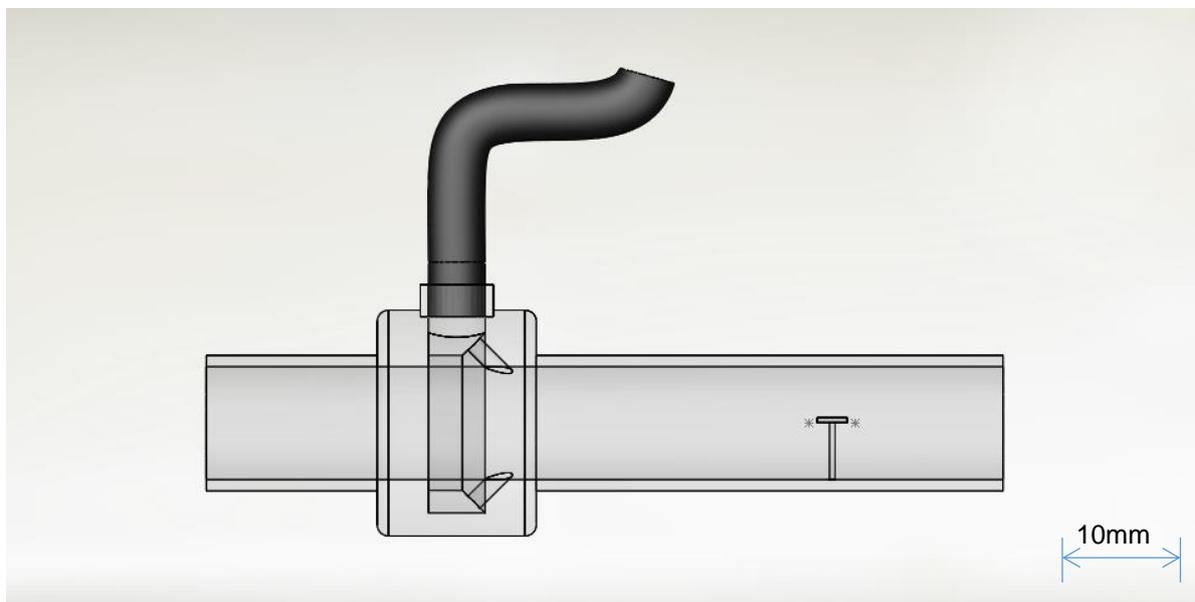

Polymeric machining can provide a lower manufacturing cost and also allows for quicker design improvement/iterations because it is a faster manufacturing process [64, 65].

#### 4.2.5.2 *Exploitation of additive manufacturing*

The device in this study was designed using the principles of DFAM as opposed to DFM. DFM is the process of designing a part or assembly with the aim of it being simple to manufacture and fabricate, which often relies on reducing geometric complexity. DFAM in some respects nullifies the need to compromise geometric complexity. The geometric complexity within the design of the novel micromixer would render it impossible to manufacture by conventional means. The design of the micromixer in this study includes four jet channels which are concealed within an annulus.

#### 4.2.6 Design of a novel micromixer

This section aims to outline the geometric design of the novel micromixer illustrated in Figure 36. The geometric complexity of this mixer required it to be manufactured through AM means. It had overhangs and internal voids which would make the device impossible to manufacture in one piece by conventional processes.

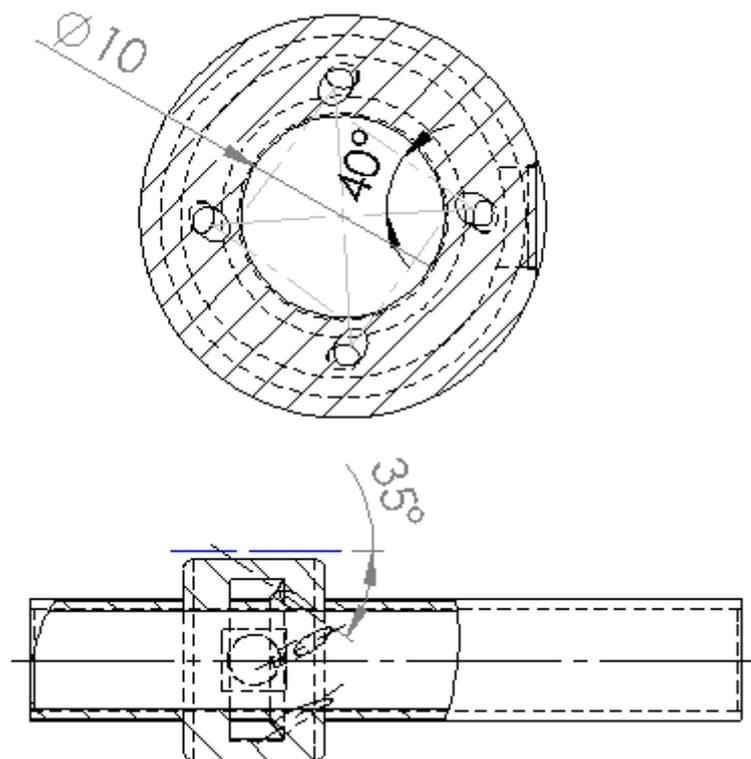

**Figure 36: Internal geometry of the micromixer**

The design of this micromixer separates from its fluid mixing counterparts in that it aims to increase mixing efficiency by generating a vortex within the main channel. It achieves this with the use of jets which are angled in the X, Y and Z planes.

Figure 37 details the geometry of the jets within the mixer to illustrate how they aim to achieve a vortex. It can be seen that the jets in this case are angled at  $35^\circ$  to the horizontal, and this is to ensure that the introduction of the second fluid does not decrease the flow rate of the primary fluid. This was decided using the rationale that if the flow rate of the primary fluid was inhibited, it would create turbulence which could influence the mixing of the two fluids. It was the purpose of this study to assess solely if the creation of a vortex increases the rate of mixing.

It can also be seen from this image that the flow of the secondary fluid is guided to follow the form of the internal wall of the main channel; this was implemented so that the device would have a good possibility of creating a vortex.

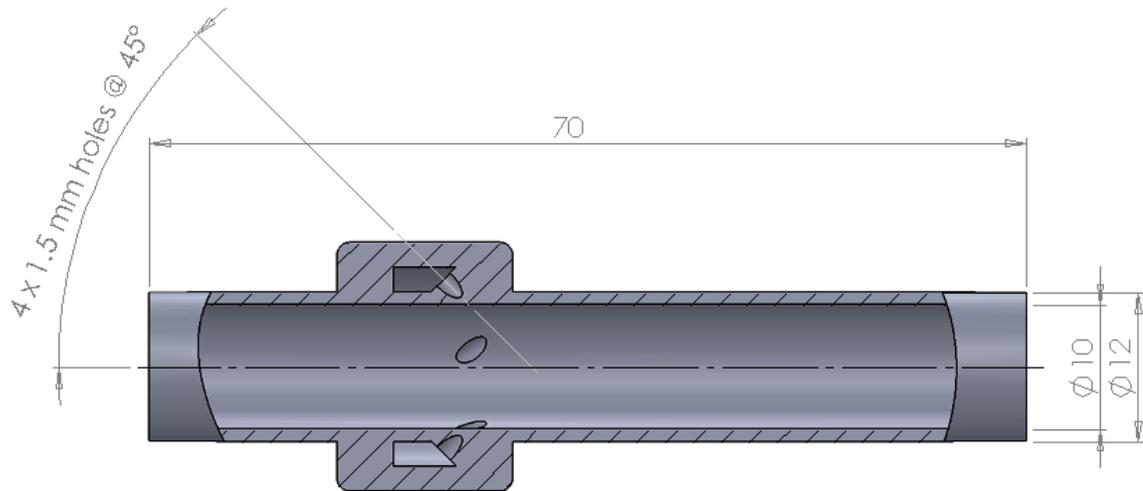

**Figure 37: Sectioned views of the mixer geometry**

Figure 38 (A) highlights with the use of a 'detail cut', the angle of one of the prototype mixers. This image shows 1.5mm jets at a  $45^\circ$  angle to the normal (denoted by the centreline). The main channel is 10mm and has 1mm wall thickness. The length of the shaft is oversized to allow for full investigation of the devices mixing properties.

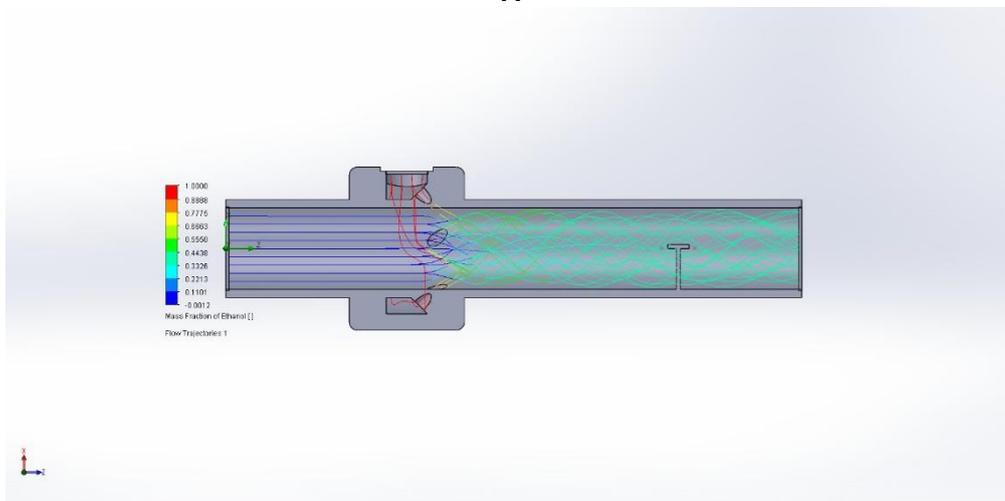

Figure 38 (B) displays the vortex created by the device and gives an indication of the devices mixing capabilities. A representation of the sensor was modelled for this trial to simulate where the mass fraction of the mixed fluid could be measured from in practice.

Figure 38 (C) shows a cut plot which briefly details the distribution of the mass fraction values within the main tube. There are no measurements shown on this figure as it is intended to illustrate the potential of the device only.

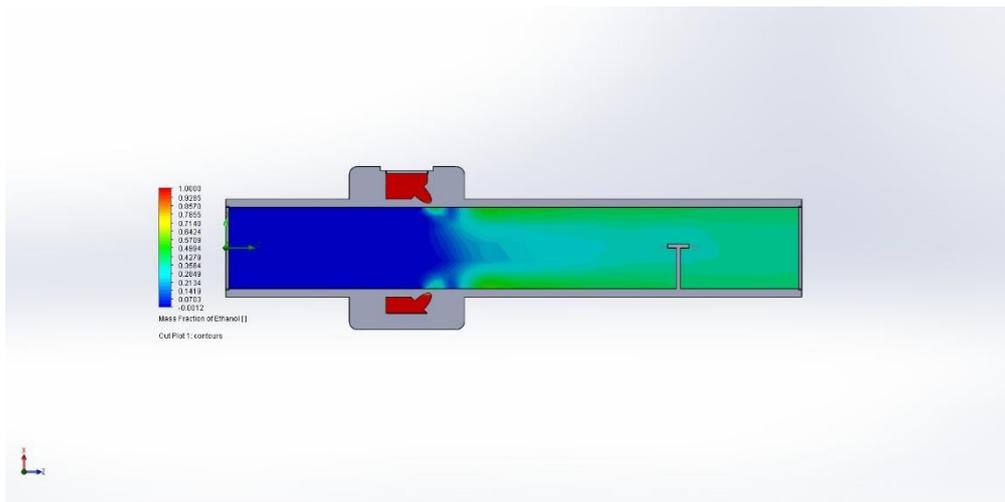

Figure 38 (D) details the mass fraction values at the point at which the sensor is situated. It can be seen that at this point, the mass fraction of the mixture is 2/3 methanol to 1/3 ethanol.

A

**Figure 38: Principle of diffusion measurement within the study**

#### 4.2.7 Mixing Efficiency

The aim of this study was to develop a novel micromixer for use in the medical and pharmaceutical industry. As such, it was deemed necessary to simulate the angles of the jet to produce an optimised prototype.

SolidWorks Flow Analysis was used at this early prototyping stage, other simulation software could produce superior analysis but at this stage in the devices development an indication of optimisation was all that was required.

##### 4.2.7.1 Mixer 4 jets at 30°

For this study into the mixing efficiency two fluids were chosen: Methanol is the main liquid which is flowing through the large bore at 2m/s and ethanol is the liquid which is injected/mixed.

The mixing effect is sampled initially at 6mm before the injection point to gain a reference from which to analyse the subsequent samples which are at 5mm stages beginning at the point of injection (+0, +5, +10, +15, +20).

Solid red is ethanol, solid blue is methanol and green represents a molecular fractal volume (Methanol) of .5. So it can be seen that (Figure 39):

Plot 1: Shows zero mixing of the fluids which was expected

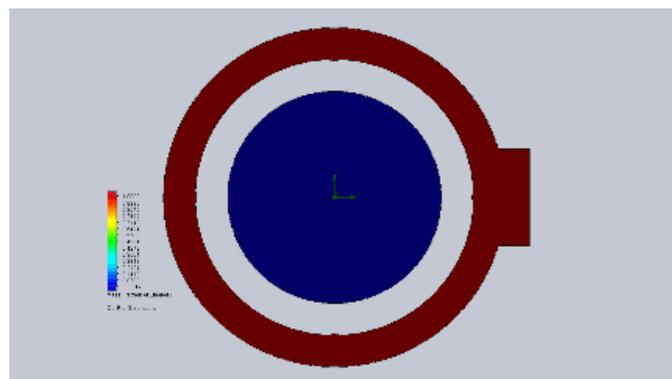

Plot 2: Shows an immediate encroachment of ethanol into the sectioned diameter of methanol. The encroachment can be described as uniform and radial diffusion at the outlet of each jet, which amounts to less than half of the total area.

Plot 3: Shows a non-uniform diffusion of ethanol into methanol. There are four areas of strong even mixing along the circumference of the plot, and a non-uniform area of concentrated methanol in the centre.

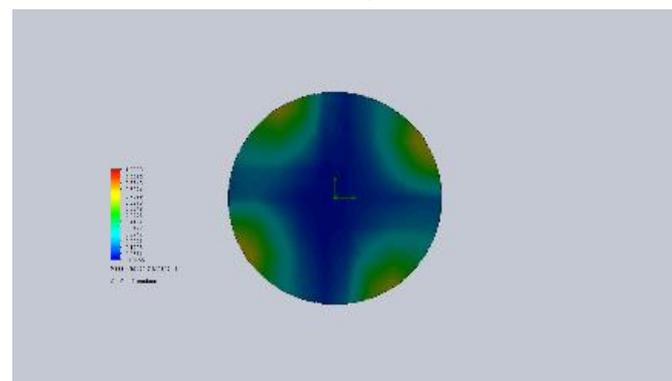

Plot 4: Shows a lessened correlation to the position of the jets with the concentration of ethanol; the concentration is more evenly distributed along the circumference of the plot and not as influenced by the outlets. The high concentration of methanol has been replaced by an area which was slightly more methanol than ethanol, however this central region appears to be uniform.

Plot 5: Shows a similar concentration distribution to plot 4, this indicates that the rate of mixing is beginning to decrease by 15mm from the jet outlets. However, the concentration of the fluids was more uniform.

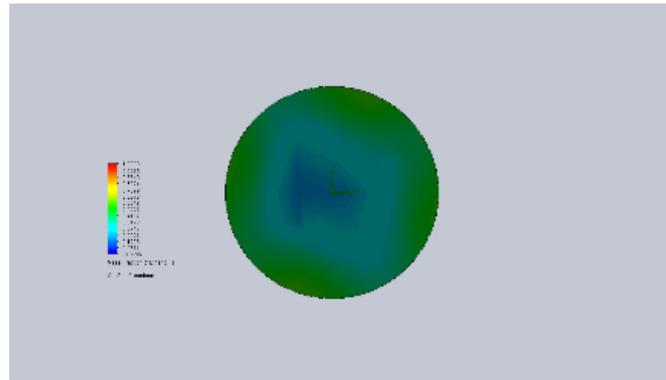

Plot 6: Shows that at 20mm from the outlets, the rate of mixing had decreased to an extent that nullified any further sampling.

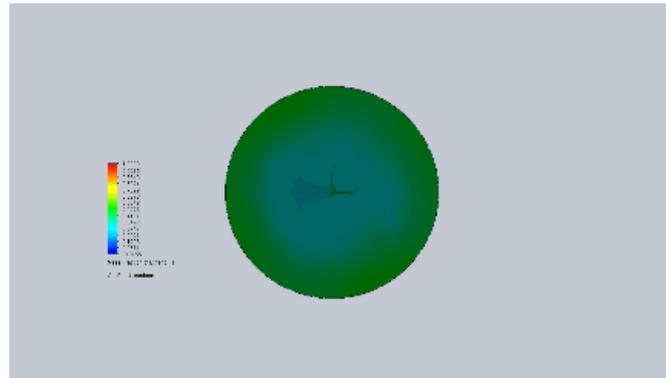

Plot 1: -6mm

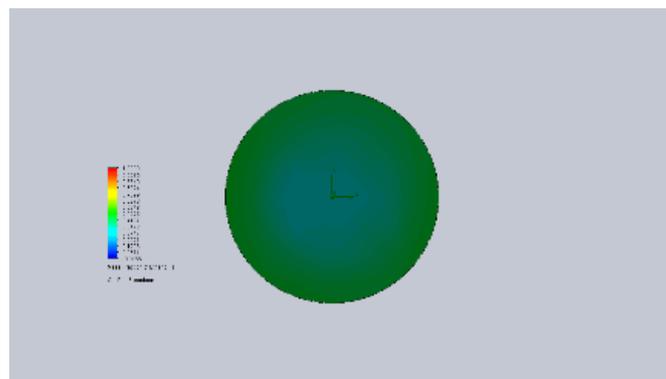

Plot 2: +0mm

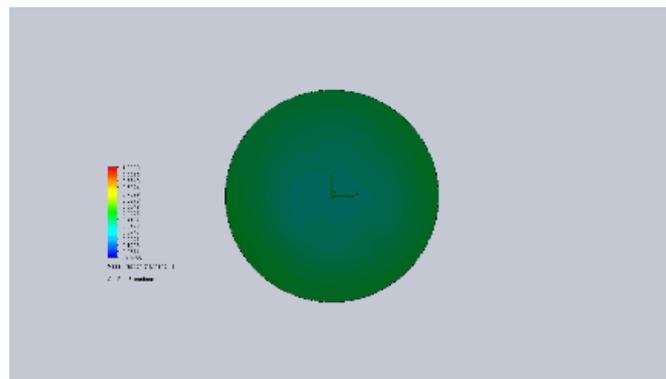

Plot 3: +5mm

Plot 4: +10mm

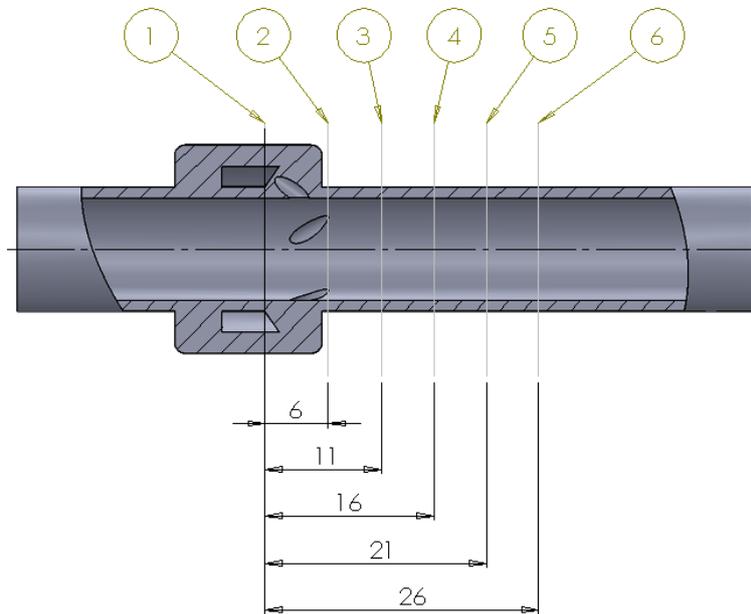

Plot 5: +15mm

Plot 6: +0.20mm

Figure 39: Mixing plots of the 30° mixer

Figure 40 shows how the model was sectioned to achieve the samples above. For each experiment, the first section was taken just before the outlet of the jets to provide a reference for each subsequent sample.

**Figure 40: Distribution of the cut plots**

#### 4.2.7.2 Mixer 4 jets at 45°

A second simulation was carried out to determine if a 45° angled jet would provide a more efficient mixing, it was postulated that there would be an optimum angle which would produce a mixed solution in the shortest distance. Below are the observations for the 45° angled jets.

Solid red is Ethanol, solid blue is methanol and green represents a molecular fractal volume (methanol) of .5. So it can be seen that (Figure 41):

Plot 1: Shows zero mixing of the fluids which was expected.

Plot 2: Shows an immediate encroachment of ethanol into the sectioned diameter of methanol, which is slightly greater than that of the 35° jets. The encroachment can be described as uniform and radial diffusion at the outlet of each jet, which amounts to half of the total area.

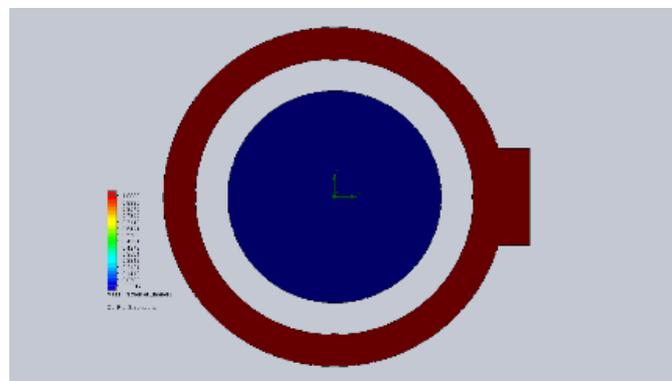

Plot 3: Shows a more uniform distribution when compared to the 35° jet simulation. There are four areas of slightly stronger mixing along the circumference of the plot, and a small area of non-uniform concentration in the centre.

Plot 4: Shows an outer ring of highly mixed fluid, along with a lessened correlation to the position of the jets with the concentration of ethanol; the concentration is more evenly distributed along the circumference of the plot and not as influenced by the outlets. The high concentration of methanol has

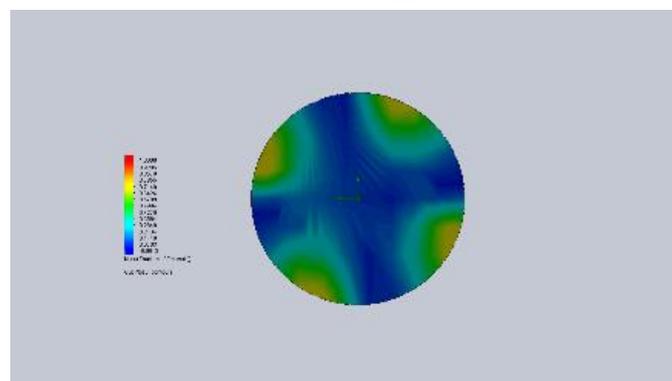

been replaced by an area which was slightly more methanol than ethanol, however this central region appears to be uniform.

Plot 5: Shows a similar concentration distribution to plot 4, this indicates that the rate of mixing is beginning to decrease by 15mm from the jet outlets. However, the concentration of the fluids was more uniform.

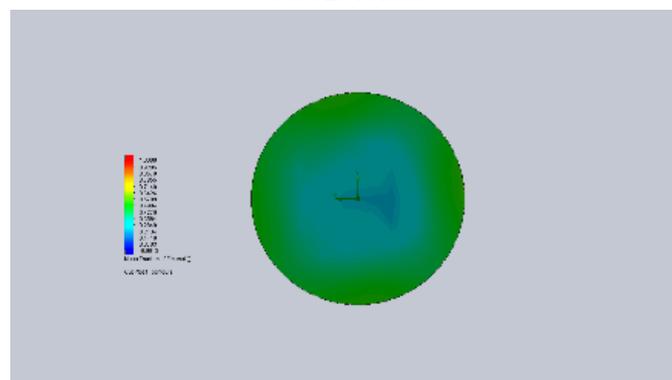

Plot 6: Shows that at 20mm from the outlets the rate of mixing had decreased to an extent that nullified any further sampling.

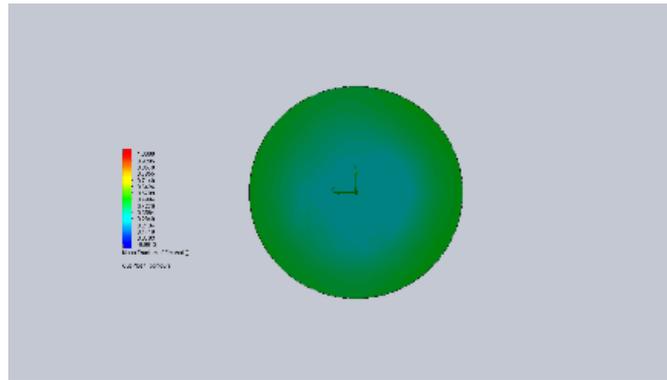

Plot 1: -4mm

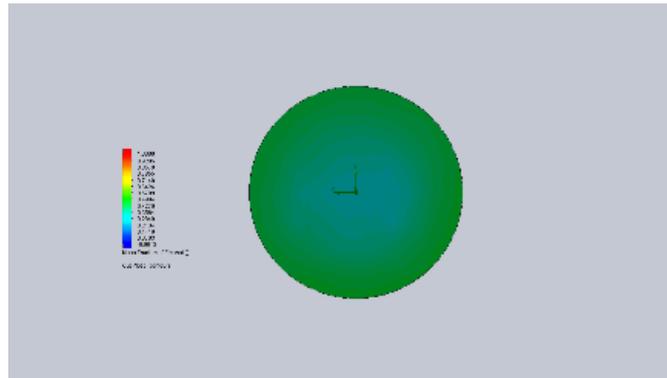

Plot 2: +0mm

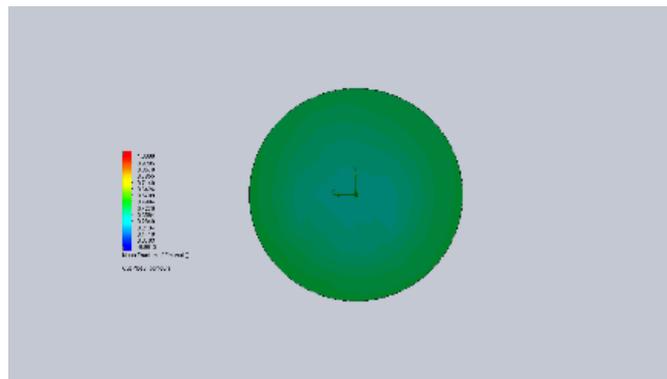

Plot 3: +5mm

Plot 4: +10mm

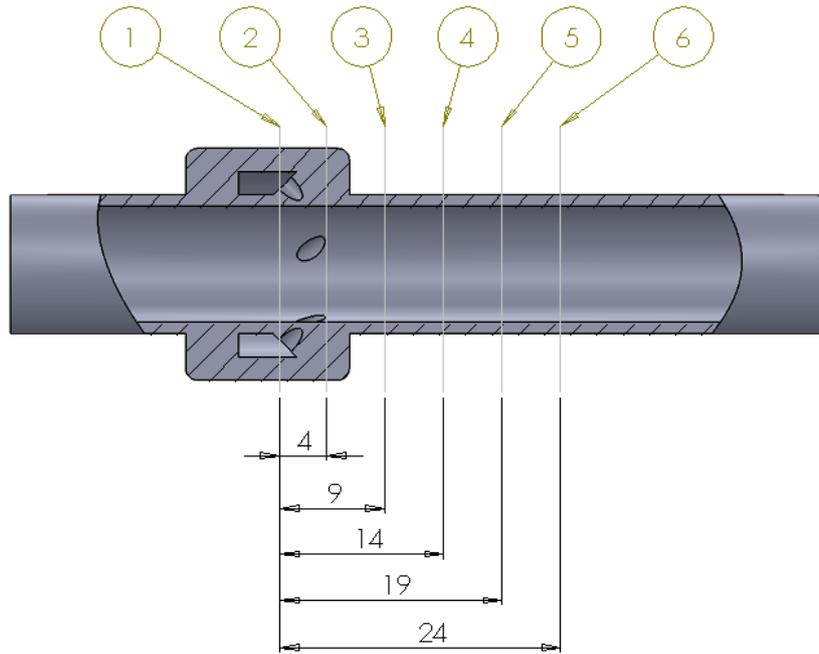

Plot 5: +15mm

Plot 6: +0.20mm

Figure 41: Mixing plots of the 45° mixer

Figure 42 shows how the model was sectioned to achieve the samples above. For each experiment, the first section was taken just before the outlet of the jets to provide a reference for each subsequent sample.

**Figure 42: Distribution of the cut plots**

#### 4.2.7.3 Mixer 4 jets 65°

A third simulation was carried out to determine if a 65° angled jet would provide a more efficient mixing. It was postulated that there would be an optimum angle which would produce a mixed solution in the shortest distance. Below are the observations for the 65° angled jets.

Solid red is Ethanol, solid blue is methanol and green represents a molecular fractal volume (methanol) of .5. So it can be seen that (Figure 43):

Plot 1: Shows zero mixing of the fluids which was expected

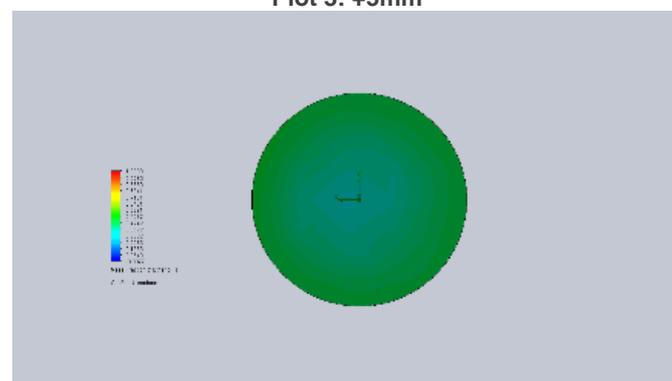

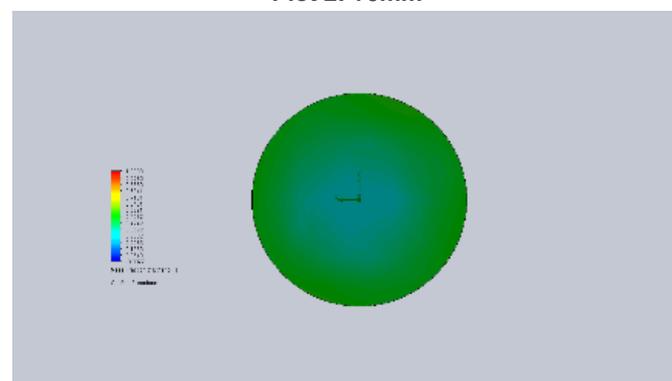

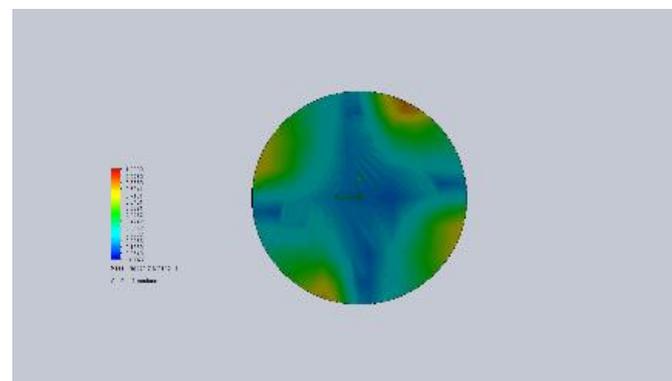

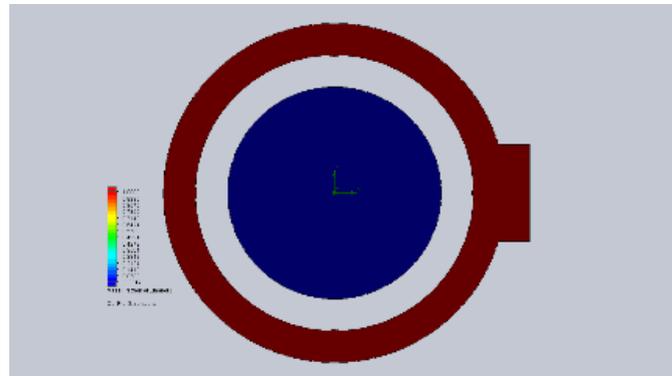

Plot 2: Shows an immediate encroachment of ethanol into the sectioned diameter of methanol, which is much greater than that of the 35° jets and also much greater than the initial mixing achieved by the 45° jets. The encroachment can be described as uniform and radial diffusion at the outlet of each jet, which amounts to more than half of the total area.

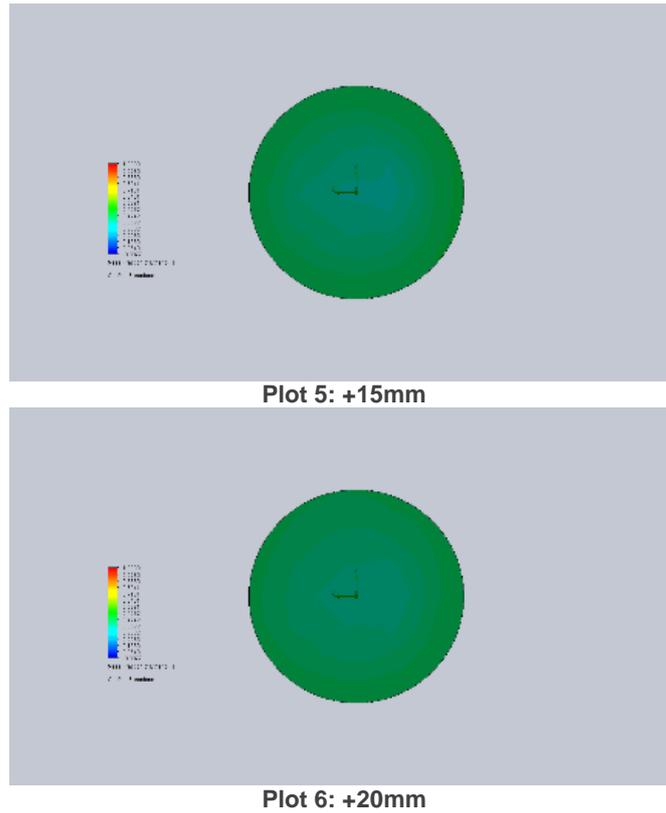

Plot 3: Shows a very uniform concentration is achieved, with no area of high methanol concentration in the centre.

Plot 4: Shows a mixture uniformity that was achieved by plot 6 in both the 35° and 45° trials.

Plot 5: Shows a similar concentration distribution to plot 4, which indicates that the rate of mixing is beginning to decrease by 15mm from the jet outlets. However, the concentration of the fluids was more uniform.

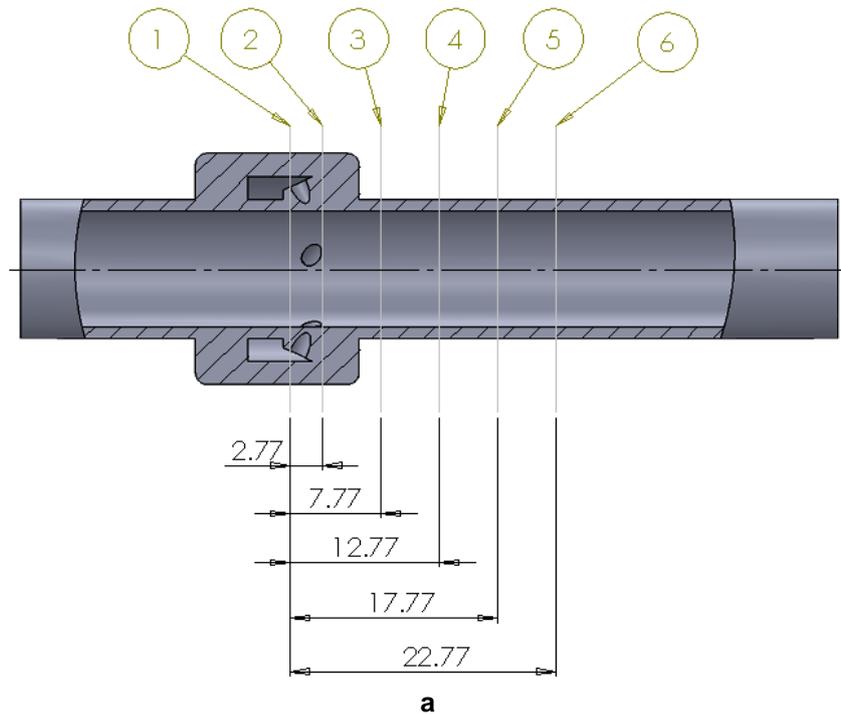

Plot 6: Shows that at 20mm from the outlets the rate of mixing had decreased to an extent that nullified any further sampling.

**Figure 43: Mixing plots of the 65° mixer**

Figure 44 shows how the model was sectioned to achieve the samples above. For each experiment, the first section was taken just before the outlet of the jets to provide a reference for each subsequent sample.

**Figure 44: Distribution of the cut plots**

#### 4.2.7.4 Mixer 4 jets 90°

A fourth simulation was carried out to determine if a 90° angled jet would provide more efficient mixing, it was postulated that there would be an optimum angle which would produce a mixed solution in the shortest distance. It was hypothesised that the 90° set-up would produce the least efficient mixing. Each of the other test scenarios produce a vortex within the chamber which serves to mix the fluids more quickly. The 90° set-up will merely inject the ethanol. Below are the observations for the 90° angled jets.

Solid red is Ethanol, solid blue is methanol and green represents a molecular fractal volume (methanol) of .5. So it can be seen that (Figure 45):

Plot 1: Shows some mixing 2mm before the outlet of the jets. This was not anticipated because it was expected that the flow of methanol would be sufficient to direct the flow of ethanol immediately upon entering the main bore. However, this observation does correlate with the postulation that the 90° jets would not create stable vortex like flow within the chamber.

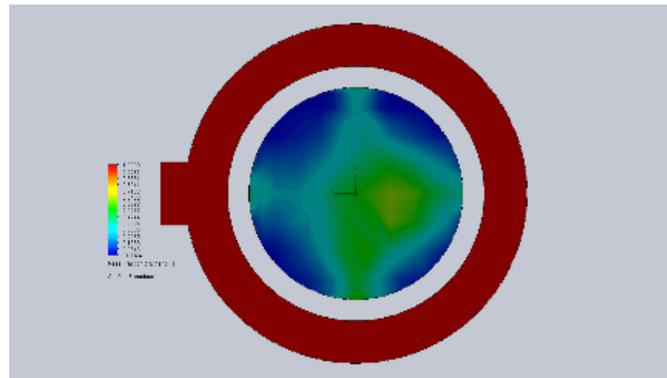

Plot 2: Shows a greater degree of mixing than observed in the previous simulation. The ethanol from the jets meets in the centre of the bore where it mixes with the methanol.

Plot 3: Shows that the methanol has been displaced to the outer edges of the bore on the upper left segment of the plot. This indicates that the set-up will not produce even mixing.

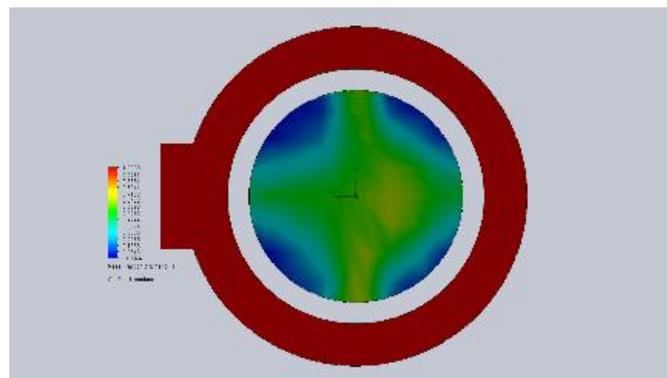

Plot 4: Shows no improvement in the mixture uniformity.

Plot 5: Shows a similar concentration distribution to plot 4, this indicates that the rate of mixing is beginning to decrease by 15mm from the jet outlets. Furthermore, the mixing is not as uniform as that achieved by the shallower angled jets.

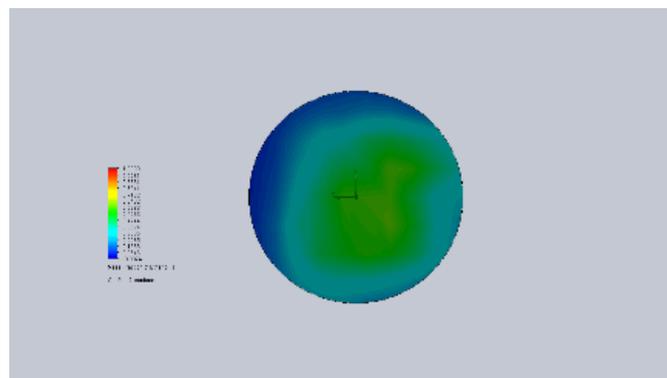

Plot 6: Shows that at 20mm from the outlets the rate of mixing had decreased to an extent that nullified any further sampling. Sufficient mixing of the fluids hadn't been achieved.

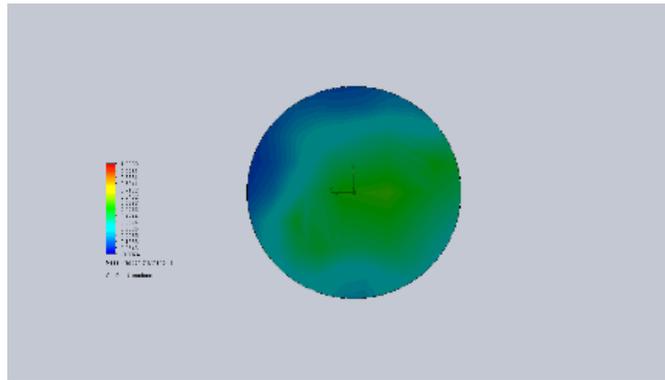

*Plot 1: -2mm*

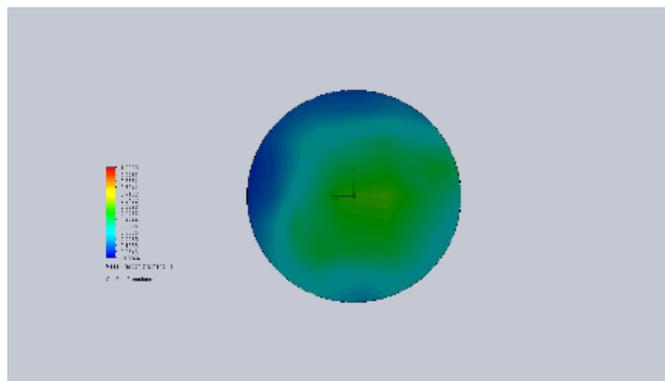

*Plot 2: +0mm*

*Plot 5: +15mm*

*Plot 6: +20mm*

**Figure 45: Mixing plots of the 90° mixer**

Figure 46 shows how the model was sectioned to achieve the samples above. For each experiment, the first section was taken just before the outlet of the jets to provide a reference for each subsequent sample.

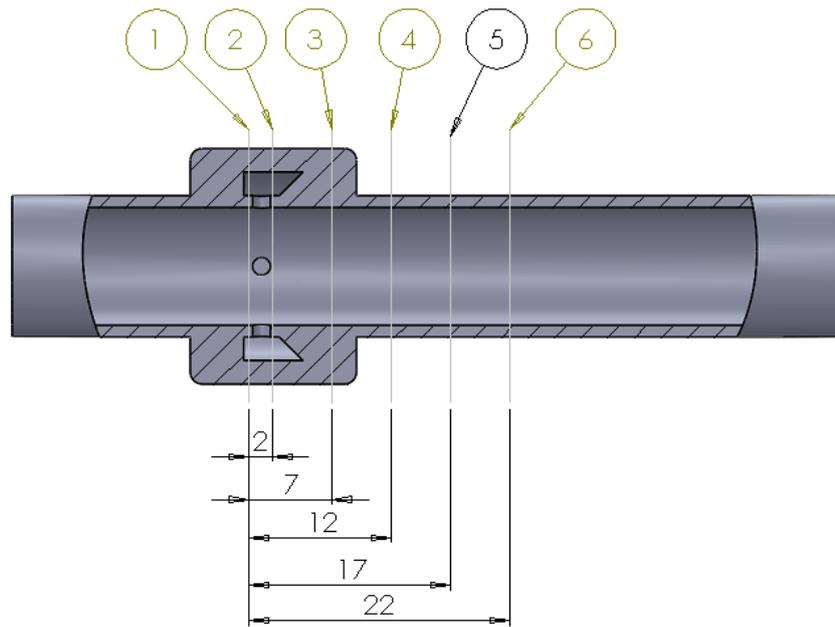

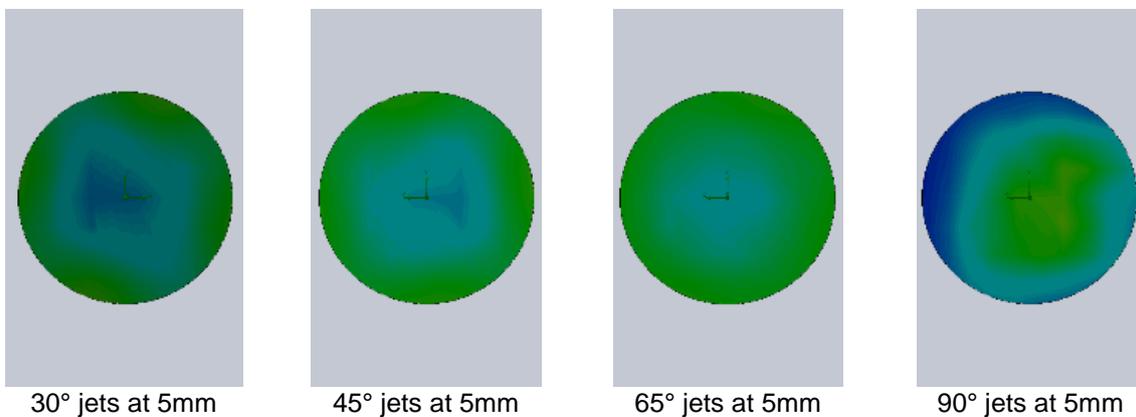

Figure 46: Distribution of cut plots

#### 4.2.8 Conclusion

Clearly, the mixing distance is shortened when the device achieves a vortex when compared with the 90° condition. The 90° trial could be categorised as a plume condition which was discussed above in the passive-injector section. The plume condition achieves mixing through increasing the mixing area of the fluid but still relies on the diffusion mixing mechanism. Whereas the vortex conditions achieved a more even mass fraction in a shorted distance, this could be attributed to the turbulent flow created by the vortex.

Below is a table to illustrate the difference in mixing efficiency of each simulated jet angle. A more detailed description is detailed earlier in the chapter for each specific jet angle.

30° jets at 5mm

45° jets at 5mm

65° jets at 5mm

90° jets at 5mm

Figure 47: comparison of angled jets at 5mm mix distance

The prototype was manufactured using the SLS process; this was the most appropriate fabrication method which was available because it did not require the use of structured supports. The powder itself was the support which could then be easily excavated from the cavity. The material used was Nylon-12, which can leave a porous component, therefore it was not ideal to test the theory behind the design. The jet geometry was non-uniform and would have acted as holes rather than jets; an investigation into the optimum jet geometry for AM is needed.

#### 4.2.9 Further work

The prototype model required further optimisation and the material selection must go beyond what was available towards a waterproof material that can be printed to an appropriate resolution. Materials which achieve this are available commercially at AM service bureaux providers. For example, the 3D Printing service Shapeways has a range of watertight acrylics which allow for a minimum feature size of 1mm.

A more detailed analysis of the output of each mixer would be appropriate. The simulation was basic and provided an indication only of the possible benefits in creating a vortex to increase mixing rate. A more in depth study using a more sophisticated fluid dynamics software such as ANSYS or COMSOL would be appropriate.

Following further simulation, a wider array of fluids should be sampled to build a foundation of consistency which proves the concept. Physical trials should only be embarked upon when the simulations have strongly indicated the concept's validity.

A mathematical description of how the device functions would help to develop a more efficient device and benchmark the device against its current competitors within the macromixing market. This mathematical analysis would follow the simulation stage. Since the degree of complexity outweighs the usefulness of the mathematical analysis during the proof of concept stage. It is envisaged that the analysis will be simplified into a 2D plane and will initially investigate the turbulent flow around the jet nozzle. This simplification would be an essential first step into the further investigation into the phenomenon of vortex mixing within small diameter pipes.

An investigation of how the characteristics of the micromixer change as the jets and channels become narrower may be appropriate as the characteristics will change as the device moves towards the nano range of micromixing. This could require design adaptations or may result in a specification which dictates the devices suitability within a particular range. This could help the device corner a certain area of the mixing market.

## **5 DESIGN FOR ADDITIVE MANUFACTURE OF A CLINICAL RECONFIGURABLE CELL CULTURE BOX**

### 5.1 Background

The brief for this study was to design a reconfigurable cell culture box. The concept behind the cell culture box envisaged that it would be used in the medical research sector to improve the adaptability and re-configurability of cell culture experiments. The brief included a rough sketch of the device and details of the design concept were provided. From this, a more detailed design was constructed in the 3D modelling software SolidWorks, which included concept designs for a cell culture block arrangement.

The collaborating partner is a spinout company of Lancaster University. As a research and development company, it has access to state-of-the-art research facilities and benefits from scientific collaboration with world class scientists and research centres. Currently the company is focused to further develop and promote its paradigm shifting invention that has extensive applications in pharmaceutical and nano-biotechnology research.

The brief for this study was to generate concepts based around an initial sketch for a cell culture device, which will allow a user greater flexibility when conducting biological experiments

The company required the device to be modelled in 3D so that a set of photorealistic renderings could be produced. These images were then to be used as artwork in future funding applications.

The outcome for this study was to develop concepts for a reconfigurable cell culture box with geometrically complex features which would only be capable of manufacture using an AM approach, and to produce a set of photorealistic renderings. Further to this, a set of manufacturing drawings were produced for the outer case of the device. It was envisioned that a prototype would be made from clear acrylic for demonstration/testing purposes.

One of the unique design features of the device is the honeycombed cell blocks, which provided structure to media with a gelatine like consistency. The cell blocks were suitable for AM because of their complex geometry. A series of prototype blocks were produced to determine the ideal wall thickness and the ideal structure of the supports. These were produced using both SLS and SL.

Figure 48 shows an isometric view rendering of the completed reconfigurable cell culture box. As stated above, this was to be used as artwork to apply for funding to further develop the concept. The renderings were created in the SolidWorks add-in software, PhotoView 360. This program allows for the adjustment of lighting, camera angles, shadows and materials, amongst many other features.

## 5.2 Creation of photorealistic renderings

### 5.2.1 Applying appearances

Initially the appearances of each of the components within the image must be specified. SolidWorks provides a directory of material choices ranging from metals through to plastics. Glass of varying colours were used to represent the gelatine like medium, the cell box was represented by transparent polycarbonate and the cell blocks and divides were represented by medium gloss white plastics. The colours used in the rendering are not completely representative of the materials that will be used in practice but it was decided that the aesthetics of the rendering was of paramount importance due to its future use in funding applications.

Figure 48 shows the selection of the discussed materials.

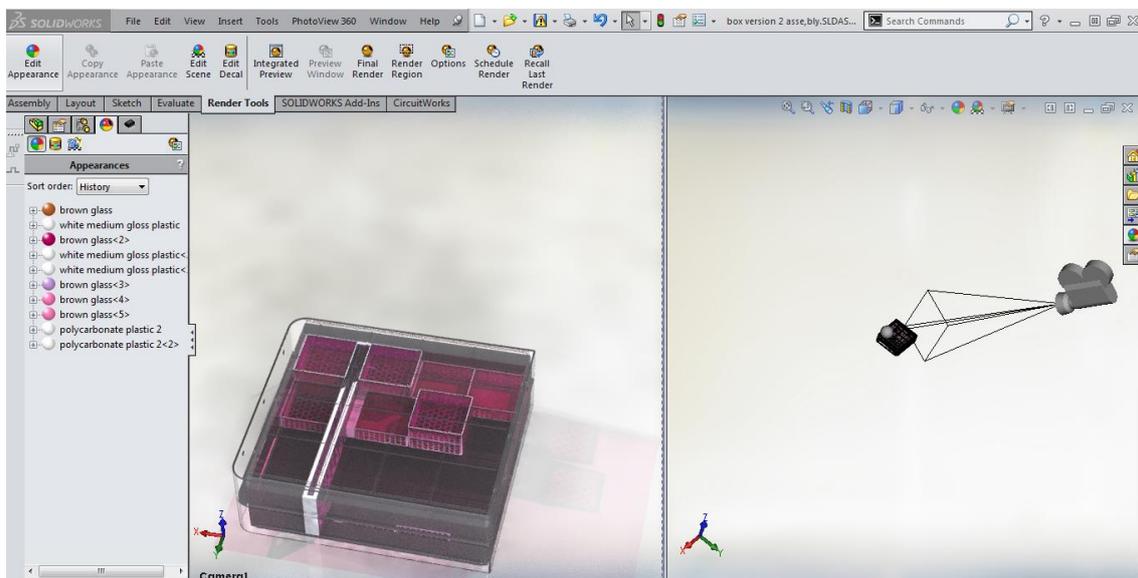

Figure 48: Selection of materials

### 5.2.2 Scene set-up

Careful preparation of the scene ensures a more realistic rendering. The initial step was to ensure that the cell box correctly interfaced with the floor of the scene. To do this the basic settings tab was located, the floor section was navigated to where the select face option can be selected. The base of the cell box was selected with zero offset. This allowed the cell box to sit as if on a surface. Further to this, the floor reflections were turned on to give the appearance of a slightly reflective surface.

A '3 Point Beige' scene was applied to the rendering. SolidWorks Scene backgrounds consist of lighting, hue, light intensity and in some cases background images, for this rendering a plain background was chosen so as not to distract focus from the device.

A camera was added to give greater manipulability of the scene. Within the camera setting it is possible to alter the field of view, change the depth of field, apply a focal point and accurately position the device in the centre of the scene. The addition of the camera also splits the workbench into two pains so that, by utilising the integrated preview option, the device could be viewed as a partial render in real time. This allowed for easier application of addition lighting because it displayed how each additional light would affect the scene.

Additional lighting was added to give the image more depth, it was important to utilise this feature because there were many translucent faces within the rendering. Carefully positioned additional lighting sources enhanced the image by highlighting the refracted structures within the cell box.

Figure 49 shows the selection of the bottom face of the device which was specified as the interface with the floor of the scene.

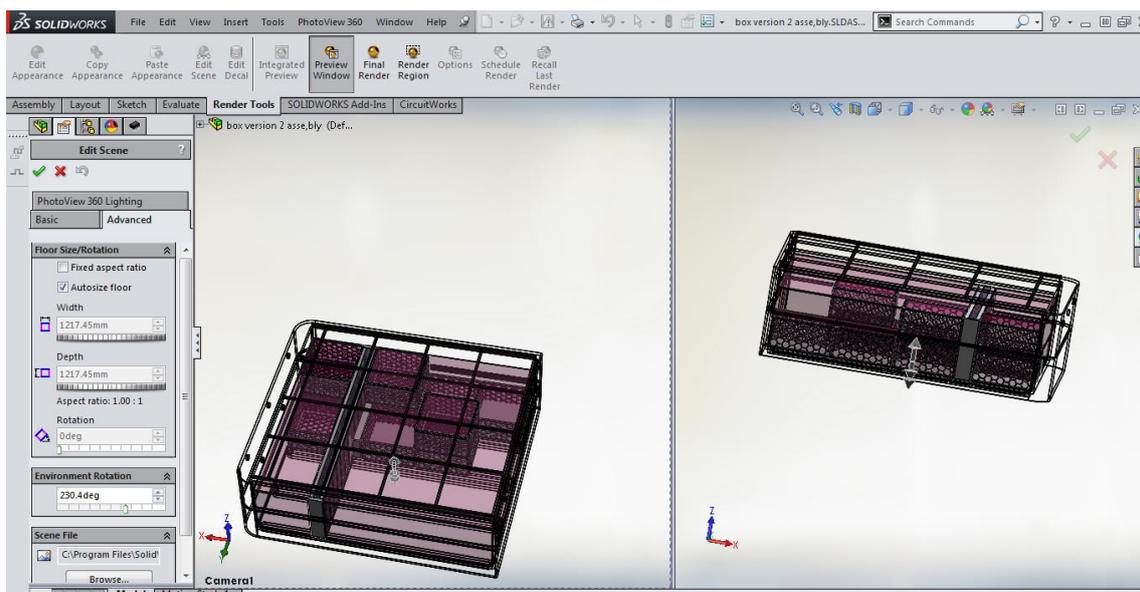

Figure 49: Scene set-up

Figure 50 shows the application of the camera settings. Many of the settings were left as default, but the depth of field and area of focus were altered extensively to achieve a realistic rendering.

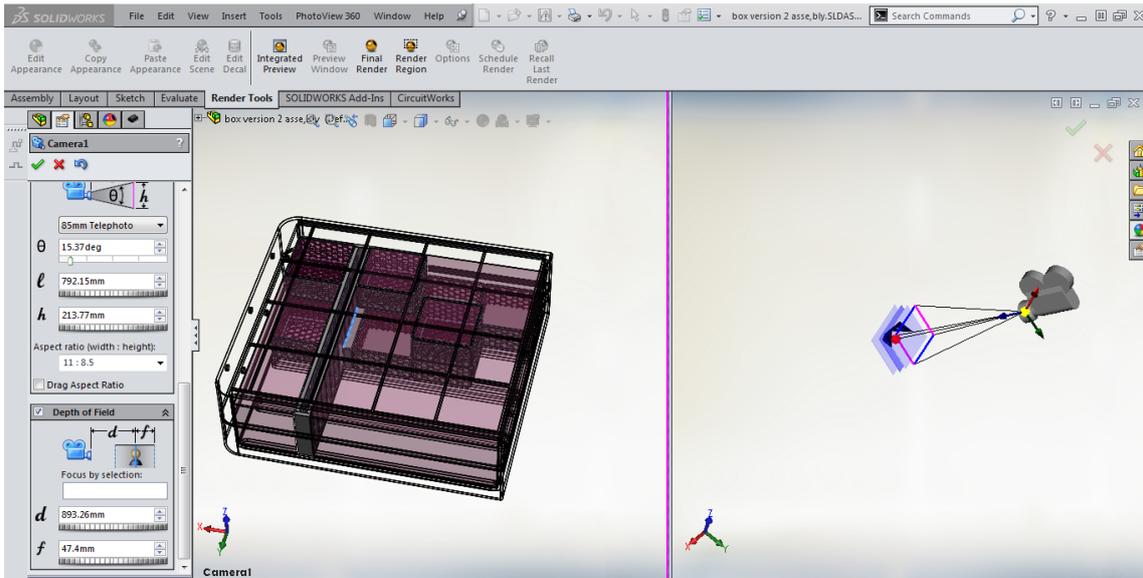

Figure 50: Camera set-up within the scene

Figure 51 shows the addition of extra light sources; these highlight how refraction affected the appearance of the structures within the cell box.

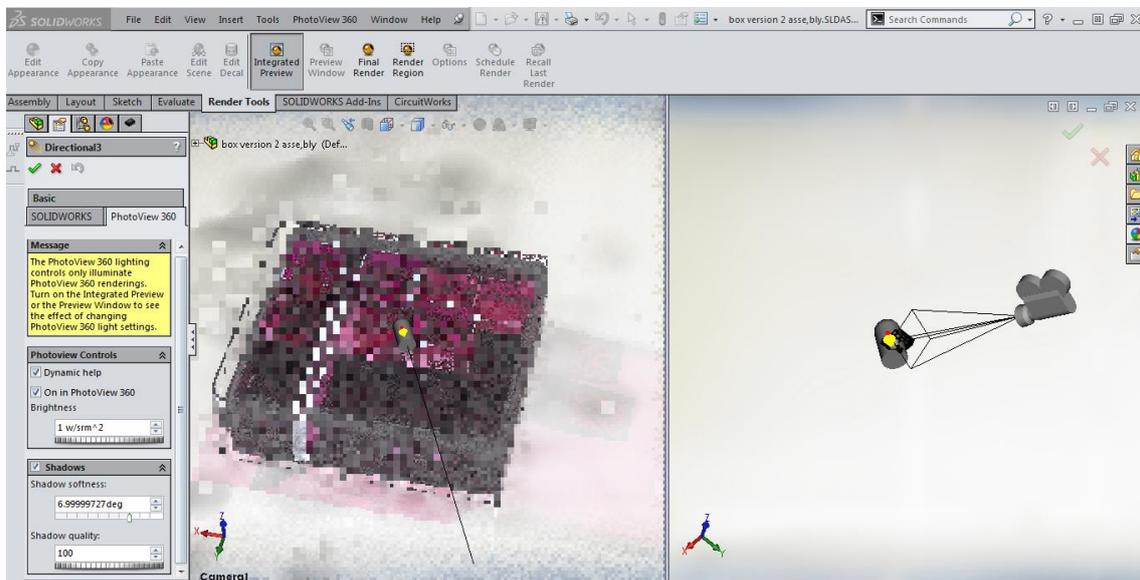

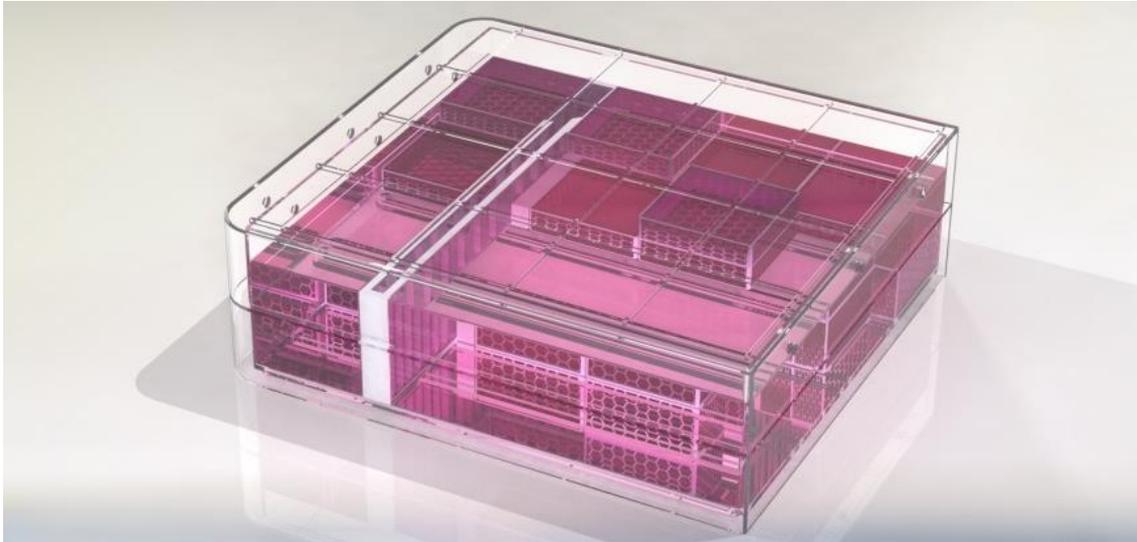

Figure 51: Addition of light sources

### 5.2.3 Rendering generation

The renderings were produced utilising the highest quality settings within PhotoView 360. The renderings took approximately 240 minutes to complete. It can be seen from Figure 52 that the box is

sat on a slightly reflective floor. The scene is neutral and does not detract from the focus of the image. There are multiple shadows from multiple light sources and the refraction of the glass creates a realistic optical illusion.

**Figure 52: Photorealistic rendering of the cell box**

Figure 53 shows a partial exploded view of the cell culture box. It can be seen from this image that the lid has segments with which to add labels, these segments could simply be numbered and referenced within the experiments literature or they could have detailed printed labels attached to them which would allow the user to identify what is in each compartment.

It can also be seen from this image that both the upper and lower sections of the box have three holes located on the left and right, these holes are intended to allow the release of any gasses produced by the experiment. Without these holes the lid may be jettisoned allowing the culture to be exposed to potential contamination.

The design also incorporates the introduction of a box dividing barrier which enables the user to separate the box into two sections therefore allowing for two experiments to be carried out concurrently. Both experiments would be influenced by the same environmental conditions but could have separate variables. This function is not currently available with standard cell culture boxes. Further to this the image below also shows the use of an individual block barrier, this would serve to limit the interaction between single blocks. This adds to the configurability of the cell box and thereby allows for more adaptable experiments.

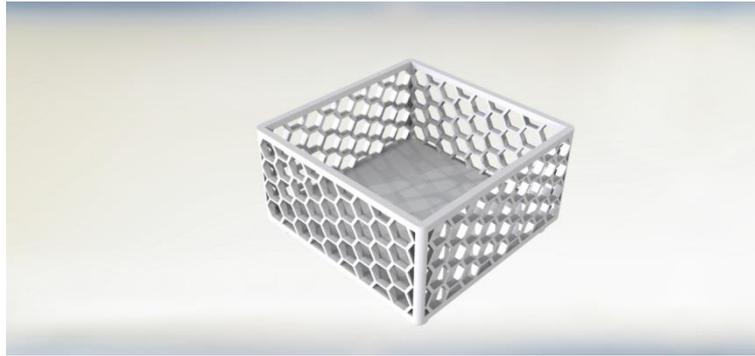

**Figure 53: Photorealistic rendering with lid exploded view**

### 5.3 Development of culture blocks

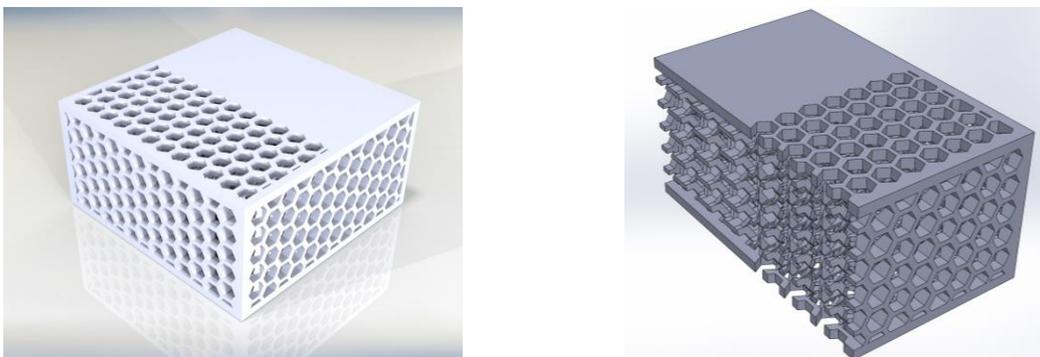

The design specification for the cell blocks was to create a structure that could support a medium which has gelatine like consistency, and develop a system by which the blocks could be reconfigurable within the cell culture box. This could be achieved by stacking and through the development of a slider system.

The cell block displayed in Figure 54 shows a block which aims to achieve the above design criteria. It has honeycomb structured outer walls to support the material, the gaps are important to allow for diffusion between desired cells. The block also has pins underneath which lock into the cell box to allow for the device to be reconfigurable.

**Figure 54: Cell block concept design**

The concept block (Figure 55) was designed to show what is geometrically possible with the utilisation of AM within this application. This block has complex inner geometry which could support a relatively non-viscous medium. The section view shows the complexity of the geometry. This geometry is only achievable using AM. The block also incorporates a blanked out section which could be utilised to limit interaction between cell blocks. This concept would require the use of high tolerance SLS; this is due to the unsuitability of techniques which require support material. Support material would be difficult to remove during post processing.

**Figure 55: Second concept design**

Figure 56 shows a concept design which would limit the interaction between two stacked blocks. Within the design brief it was specified that concepts should be developed to meter the interaction between stacked blocks. This concept utilises the pins located on the bottom of the blocks, which have the dual purpose of locating into the cell box channels, to fix a separating plate into position between the stacked cells.

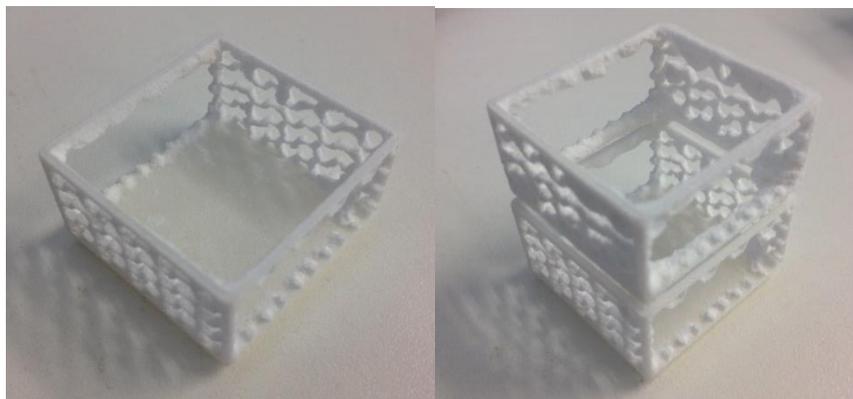

**Figure 56: Exploded rendering of the cell block divider concept**

#### 5.4 Manufacture of the prototype blocks

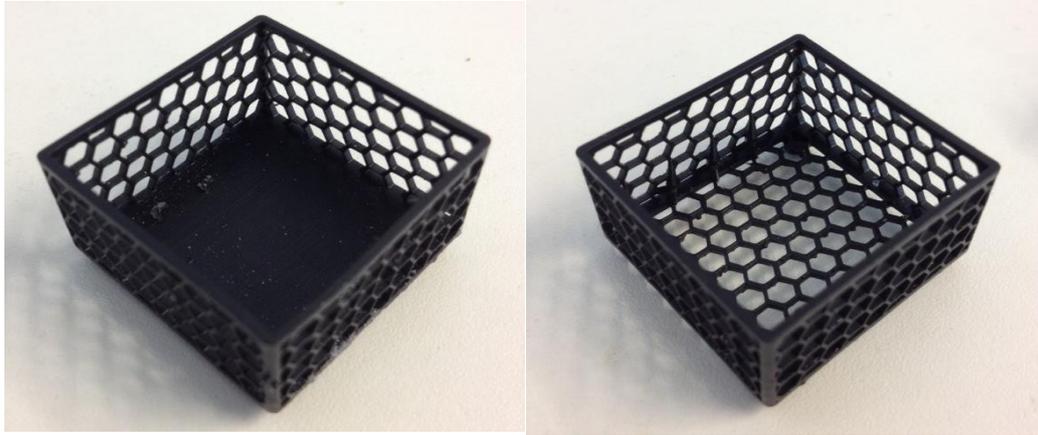

The prototype culture box was initially manufactured using the SLS technique, where the minimum feature size producible on the Sinterstation machine was 1mm, so the design was on the cusp of the capabilities of the machine. As can be seen in Figure 57, the intricate honeycomb structure failed to build. The honeycomb structure failed during the post processing stage, as the structure was extremely brittle. It can be seen that the outer box structure had built with sufficient strength to maintain its shape but the honeycomb panels had either failed to build or failed to build with sufficient strength to survive post processing.

Because of this SLS failure, it was decided that SL would be a more appropriate method to prototype the boxes. The SL technique has a resolution of 25 $\mu$ m, so the intricate structure was comfortably within the capabilities of the machine.

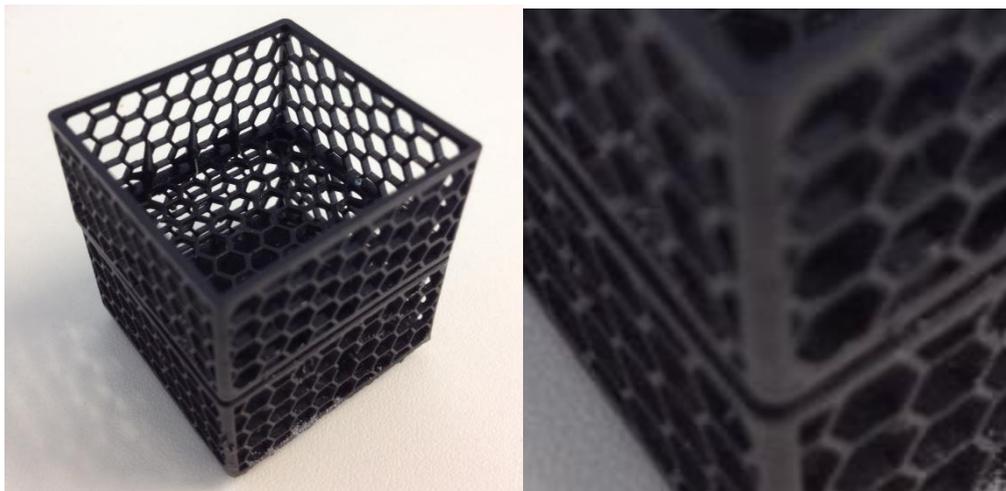

**Figure 57: Failed SLS build of the cell blocks**

Figure 58 shows two prototype blocks manufactured utilising the SL technique. It can be seen that the honeycomb structure has built successfully, along with the box edges and the base of the block which is intended to interface with the cell box floor.

**Figure 58: Successful build of the cell blocks utilising the SL technique**

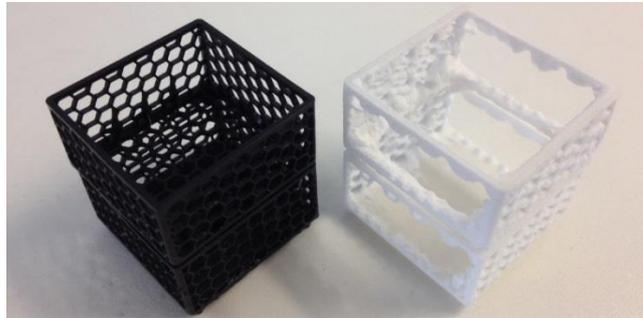

Figure 59 shows how the two boxes connect in a stacked configuration. This configuration allows for an extra dimension in the design and implementation of cell culture experiments when compare with conventional cell culture boxes. The pins help to locate and fix the upper box securely into position while the pins on the lower box locate the stack within the cell culture box using the channels.

**Figure 59: Stacked cell blocks**

Figure 60 shows the two builds side by side. It is easy to see that SL produced a far superior prototype. SL produced a consistent and uniform block whereby all features were complete and without defect

whereas SLS only produced a consistent outer edge and a failed to successfully build the honeycomb structure.

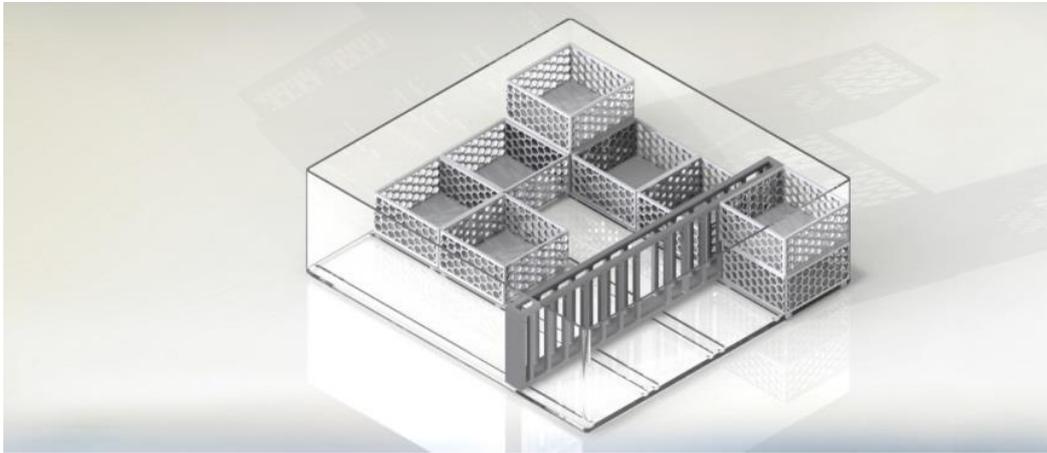

**Figure 60: Side-by-side for comparison**

## 5.5 Assembly of cell culture box/feature overview

- **Box channels:** Channels which run perpendicular to each other and adjacent to the cell box divider provide structure to the cell culture box. These channels interface with the pins located on the base of the base blocks.
- **Base blocks:** The base blocks have honeycomb structured walls which serve to support the gelatine like medium and also allow for a diffusion surface between pairs of blocks. The base blocks also have a solid base because there isn't a requirement for the base blocks to have a diffusion surface with the base of the cell culture box.
- **Top level block:** The top level block was identical to the base block in all but one respect. The top level block has a honeycombed base to allow for diffusion between the upper and lower levels.
- **Single block divider:** This feature gives the user the option to limit the interaction between two blocks.
- **Stack divider:** The stack divider is a solid piece with four location holes which interface with the pins of the top level block. This feature allows the user to limit the interaction between a top level block and a base block.
- **Cell box divider:** The cell block divider creates a break between two sides of the cell culture box. The feature consists of a rectangular outer structure with vertical supports. The feature is hollow to allow the user to add a solid partition if required.
- **Gas release holes:** The gas release holes serve to prevent the lid from jettisoning from a build-up of internal pressure created by the production of gas during a cell culture experiment. The holes allow the gas to escape thereby keeping the pressure equal.
- **Label indicators:** The label organisation structure on the lid of the cell culture box allows the user to easily label and therefore keep track of complex culture experiment arrangements.

Figure 61 shows a simple culture experiment arrangement. It can be seen that the cell blocks can be reconfigured to suit multiple experiments.

**Figure 61: Example of a cell box assembly**

## 5.6 Conclusions

There were two main aims to this study:

- 1) Develop concepts for a reconfigurable cell culture box;
- 2) Produce a set of photorealistic renderings for use in future funding applications.

The first aim stated above can be considered a success, as a multitude of concepts were developed, all of which are guided towards reconfigurability. The cell blocks were produced utilising AM methods, initially through SLS which was unsuccessful followed by SL which produced a satisfactory prototype. The base and top blocks which were produced interfaced perfectly which was testament to the accuracy and resolution of the SL process.

The second aim stated above was achieved by utilising PhotoView 360. The images are of sufficient quality to form part of future funding applications for the external industrial collaborator. The images could be improved further by the Implementation of more sophisticated stand-alone rendering software.

## 5.7 Future work

To validate the concepts produced in this study, it would first be appropriate test the cell blocks, which are designed to support the gelatine like medium. The validity of the system is hinged upon the success of the block design, so if following testing, the blocks are deemed fit for purpose, then the cell culture box and all other components should be manufactured.

Further development should be applied to the dividers; these were secondary considerations during the concept phase because a higher degree of importance was placed upon the blocks and the cell culture box. The basic principle of a divider which is hollow to allow the insertion of a partition is believed to be sound but the concept requires work. For this reason, a detailed description has not been provided within the design section.

The rendering of the photorealistic images could be improved with the use of more sophisticated software. Photoview 360 can achieve high quality images, as can be seen in the study but the level of detail is second to that achievable in software packages such as 3D Studio Max.

3D Studio Max is a premium rendering software from Autodesk which is used in the videogame and film graphics industries. However, the use of PhotoView 360 was sufficient for the production of the images in this study. The additional time to produce them utilising more sophisticated software would not be outweighed by the improvement in quality.

## 6 **DISCUSSION**

The research and activity detailed within this dissertation aimed to show how AM could potentially be utilised within the medical and healthcare industry. It did this by targeting three major areas:

1. The development of surgical tools;
2. The creation of 3D models from MRI data;
3. The development of novel medical devices.

Each of the studies served an initial research project, following from this initial prototyping/research phase, further development has taken place. In some cases it has taken the form of a dedicated PhD project and in other cases it has taken the form of further research grant proposals.

In the development of a novel surgical tool, this study considered how AM could be utilised to provide a proof of concept. This was successful in that the design was approved by the external collaborator and an AM prototype was produced.

In the creation of a 3D model from MRI data, the study showed how this could be achieved utilising free-source software and made recommendations as to where commercial software may produce superior results. However, a 3D model was created which is not commonplace within the medical sector. This model provided the patient with the desired appreciation of their medical ailment. As such, this case study was considered to be successful with the caveat that if further modelling was to be required, it may be appropriate to use more sophisticated software. However, the requirements of this study did not specify that the model had to be particularly geometrically accurate because it was not to be used as a surgical guide, it was for information only.

In the development of novel medical devices, this study considered two separate cases. The first was the development of a novel mixing device which utilised the creation of a vortex within a pipe to increase mixing efficiency when compared to other micromixing devices. This study simulated how the device performed for different jet angles but did not directly compare the novel device's mixing ability to that of any current micromixing devices. This was not carried out for two reasons:

1. The definition of micromixer (defined in case study three) is wide reaching, so it was inappropriate to compare to a single device;
2. The novel vortex mixing method was unique among micromixing devices which meant that a direct comparison was not achievable.

The case study succeeded in developing a novel device which could only be manufactured utilising AM methods. There are areas with which the study could be progressed further, in that physical testing could be carried out. Further to this, research into the selection of an appropriate device to benchmark the novel mixer against should be carried out. The selected device should be currently on the market.

The second case study which investigated how AM could be used to develop a medical device, was the development of a novel cell culture box. The brief required the production of concepts which would

allow the device to be reconfigurable and flexible to allow for greater freedom when designing cell culture experiments. The study detailed this process which utilised 3D modelling and AM.

This study succeeded in achieving a reconfigurable cell culture box which satisfied the expectations of the external collaborator. Extensive 3D modelling was carried out to facilitate the creation of photorealistic renderings which the external collaborator could use in applications to fund the further development of the idea.

The study could be expanded into more detailed development of the dividing sections; the sections were an addition by the external collaborator at a late stage and would require additional time to conclude the development. However, the principle behind the divider concept was agreed to and the collaborator was enthusiastic towards the idea for further development.

The major area in which this study requires expansion is by the initiation of physical testing. The cell blocks are currently concept designs. The designs should be validated with the completion of physical testing.

The study as a whole aimed to show the relevance of AM within the medical industry. There is no shortage of literature which allude to AMs applicability in this industry, but this dissertation provides case studies which detail how it can be used to solve real-world challenges within the sector.

The dissertation is not exhaustive of all the applications in which AM could be utilised within the medical industry and indeed the studies in which it focuses are not exhaustive within themselves, but each study does indicate the validity of an AM approach in the solving medical challenges. In this respect, the study fulfils its aim to show that AM can be utilised within the medical sector.
