HIIT: high-intensity interval training
IFNγ: interferon gamma
IL: interleukin
MCP-1: monocyte chemoattractant protein-1
mRNA: messenger ribonucleic acid
N2: nitrogen
O2: oxygen
PPO: peak power output
RER: respiratory exchange ratio
RPE: rating of perceived exertion
SD: standard deviation
SIT: sprint interval training
TNFα: tumour necrosis factor alpha
VEGF: vascular endothelial growth factor
VO2: oxygen uptake
VO2peak: peak oxygen uptake
ABSTRACT

Purpose: The present study aimed to investigate the effect of age on circulating pro- and anti-inflammatory cytokines and growth factors. A secondary aim was to investigate whether a novel sprint interval training (SIT) intervention (3 x 20 s ‘all out’ static sprints, twice a week for 8 weeks) would affect inflammatory markers in older men.

Methods: Nine older men (68 [1] years) and eleven younger men (28 [2] years) comprised the younger group. Aerobic fitness and inflammatory markers were taken at baseline for both groups and following the SIT intervention for the older group.

Results: Interleukin (IL)-8, vascular endothelial growth factor (VEGF), and monocyte chemoattractant protein-1 (MCP-1) were unchanged for the older and younger groups at baseline (IL-8, p = 0.819; MCP-1, p = 0.248; VEGF, p = 0.264). Epidermal growth factor (EGF) was greater in the older group compared to the younger group at baseline (142 [20] pg.mL⁻¹ and 60 [12] pg.mL⁻¹ respectively, p = 0.001, Cohen's d = 1.64). Following SIT, older men decreased EGF to 100 (12) pg.mL⁻¹ which was similar to that of young men who did not undergo training (p = 0.113, Cohen's d = 1.07).

Conclusion: Older aerobically trained men have greater serum EGF than younger aerobically trained men. A novel SIT intervention in older men can shift circulating EGF towards trained younger concentrations. As lower EGF has previously been associated with longevity in C. elegans, the manipulative effect of SIT on EGF in healthy ageing in the human may be of further interest.

INTRODUCTION

Human ageing involves a loss of function of multiple physiological systems, including the cardiovascular system, respiratory system, musculoskeletal system, and immuno-senescence (Rebelo-Marques et al. 2018). Circulating cytokine dysregulation is well recognised as a consequence of biological ageing (Alvarez-Rodriguez et al., 2012). The 'inflamm-ageing' hypothesis suggests that chronic ageing is associated with increased reactive oxygen species and increased basal pro-inflammatory state (Franceschi et al. 2007). Indeed, tumour necrosis factor alpha (TNFα) is greater in 80-year-olds relative to younger individuals and greater again in centenarians. Similarly, interleukin (IL)-6 is elevated with increasing age (Bruunsgaard et al. 1999; Baylis et al. 2013; Kanikowska et al. 2014) while intracellular pro-inflammatory cytokines (including interferon gamma [IFNγ] and TNFα) are seen to be elevated in T cells of older vs young participants (Zanni et al. 2003).

The deleterious effects of ageing on immune function are linked to dysregulation of cytokines which are responsible for the promotion of the pro-ageing senescence-associated secretory phenotype (Coppé et al. 2010). It has been reported the senescence-associated secretory phenotype is promoted by excess body fat associated with increased pro-inflammatory adipokines and cytokines, such as IL-6 and IL-8, alongside cytokines such as monocyte chemoattractant protein-1 (MCP-1), IFNγ, and TNFα (Christiansen et al. 2005; Monzillo et al. 2012; Sharabiani et al. 2011; Vieira et al. 2009). This is further compounded by decreased anti-inflammatory myokine expression, which disrupts inflammatory balance, facilitating pathological developments including insulin resistance, cardiovascular disease, sarcopenia, chronic kidney disease, neurodegenerative disease, and increased inflamm-ageing of all organs (Muller et al. 2019). Moreover, growth factors, such as vascular endothelial growth factor (VEGF) and epidermal growth factor (EGF), when overexpressed, facilitate increased autoimmune diseases activity and tumorigenesis (Dasthangirisaheb et al. 2013; Kasza 2013). Concerning EGF specifically, Meybosch et al. (2019) noted significant inverse correlations between EGF (normalised for body surface area) and age, and EGF and body height. There was a notable and dramatic decrease in EGF post-puberty, causing authors to emphasise the importance of EGF in maturation and growth during the early years of life. What is unknown however, is the influence of physical fitness, physical activity levels, and exercise training on EGF.

Interestingly, whilst the ageing process is omnipresent in humans, physical activity can meaningfully attenuate the development of senescence-associated secretory phenotype (Garatachea et al. 2015). Masters athletes
possess superior muscle and cardiovascular function relative to untrained age-matched individuals, but still
show decreases in physiological function with increased age, suggesting lifelong exercise can delay, but not
prevent, ageing related changes to physiological systems, including inflammatory cytokine concentrations
(Campbell et al. 2019; Duggal et al. 2018; Elliott et al. 2017; Ganse et al. 2018; Pollock et al. 2015).

Formalised physical activity, such as aerobic training and resistance training, have been widely researched for
health promoting benefits in older populations (Chodzko-Zajko et al. 2009; Hayes et al. 2015; Hayes and Elliott
2019; Sellami et al. 2019; 2020). Previous reviews have found both aerobic and resistance training to be
effective in attenuating senescence-associated secretory phenotype development (Muller et al. 2019; Sellami et
al. 2018). Further, a review by Muller and colleagues (2019) suggests high intensity interval training (HIIT) also
attenuates the senescence-associated secretory phenotype. Previously described by MacInnis and Gibala (2016),
HIIT utilises periods of high intensity exercise interspersed by lower intensity phases of recovery. Generally,
even with lower training volumes, HIIT produces similar health benefits when compared to classical forms of
aerobic training, and has been deemed time-efficient and enjoyable in various populations (Gibala et al. 2012;
Gillen and Gibala 2014; Hayes et al., 2020; Herbert et al. 2017; Hurst et al., 2018; Ramos et al. 2015; Weston et
al. 2014). Although HIIT is effective in improving physiological function, it has been suggested the perceived
difficulty of performing HIIT coupled with complex prescription may dissuade individuals from adopting HIIT
(Biddle and Batterham 2015; Buchheit and Laursen 2013). Yet, a distinct derivative of HIIT, sprint interval
training (SIT) offers an easier to prescribe exercise format (i.e. 'all-out'). SIT has been described as enjoyable,
tolerable, and easier to prescribe than HIIT, whilst still promoting positive physiological adaptations (MacInnis
and Gibala 2016; Olney et al. 2018; Stork et al. 2018; Thum et al. 2017; Vollard et al. 2017; Vollard and
Metcalfe 2017). Therefore, it is of interest to the field of exercise science and gerontology to investigate the
effects of SIT on immune-modulating cytokines and growth factors (Hwang et al. 2020).

To separate the effect of ageing from any effect of lifelong inactivity on circulating pro-inflammatory cytokines,
anti-inflammatory cytokines, and growth factors, we aimed to first establish the effect of age on circulating
inflammatory markers and growth factors in well trained young and older men, by comparing these biomarkers
in a cohort of young men, and a cohort of older men who were all aerobically trained. A secondary aim was to
examine the effect of a novel SIT stimuli on older aerobically trained men. It was hypothesised that older men
would show elevated pro-inflammatory cytokines relative to a young cohort, and SIT would reduce pro-inflammatory cytokine concentrations.

METHODS

Participants

Two cohorts were recruited for this study, younger (n = 11; 21-34 years of age) and older (n = 9; 63-73 years of age) men, who regularly participated in a weekly minimum of 150 min.wk\(^{-1}\) of moderate or high intensity exercise for at least 6 months prior to participating in the study and continued habitual physical activity for the duration of the study. Participants were free of exercise contraindicating disease or injury as determined by a Physical Activity Readiness Questionnaire and American College of Sports Medicine pre-exercise participation screening (Riebe et al. 2015). This study was carried out in accordance with the Declaration of Helsinki and approved by the University of Cumbria Research Ethics Committee. Written informed consent was obtained from all participants prior to study commencement and subjects were excluded if they presented with atrial fibrillation. Descriptive statistics for participants are shown in Table 1, and further described in the results section. Participants attended all sessions with exercise suitable clothing and footwear. The younger cohort attended a single test session whilst the older cohort attended two separate testing sessions five days prior to, and five days after, the final SIT session of the intervention, which was 8 weeks in duration (Fig 1).
Fig 1 Schematic representation of the methodological flow. PPO = peak power output. VO$_{2peak}$ = peak oxygen uptake

Blood draws and analysis
Participants arrived at the exercise physiology laboratory between 08.00–11.00 h, following an overnight fast and having abstained from strenuous physical activity for a minimum of 48 h. Participants were reminded to maintain standardised conditions prior to each assessment point which included arriving in a hydrated state having abstained from caffeine and alcohol consumption for 24 h. Following 20 min supine rest, blood was sampled from the antecubital vein using standard venepuncture method into sterile serum separator vacutainer tubes (Becton Dickinson, Rutherford, NJ) that were kept at room temperature in the dark, for 30 min, to allow for clotting, after which samples were centrifuged at 1100 g for 15 min. Serum was then extracted, aliquoted, and stored at −80°C until subsequent analysis. Blood samples were collected at the same time of day for each
participant to control for biological variation and minimise inter-participant variation. Blood draws were completed prior to any exercise testing.

Anthropometry

Height was measured to the nearest 0.1 cm, and mass to the nearest 0.01 kg using a Seca 286 measuring station (Birmingham, UK), from which body mass index (BMI) was derived by dividing mass by the square of height (kg/m²).

Peak power output (PPO)

PPO was established using the 6 s Herbert test (Herbert et al. 2015b) on an air-braked cycle ergometer (Wattbike Ltd., Nottingham, UK), which consisted of a maximal 6 s sprint from a standing start.

Peak oxygen uptake (VO₂peak)

At least five min after PPO determination, VO₂peak was determined using a Cortex II Metalyser 3B-R2 (Cortex, Biophysik, Leipzig, Germany). Expiratory airflow was achieved using a volume transducer (Triple V® turbine, digital) connected to an oxygen (O₂) analyser. Expired gases were analysed for O₂ with electrochemical cells and for carbon dioxide CO₂ output with an infrared analyser. The Metalyser was calibrated according to manufacturer's guidelines prior to each test. After a 60 min warm-up period, the O₂ and CO₂ sensors were calibrated against environmental air in addition to reference gas of known composition (5% CO₂, 15% O₂, and 80% N₂) with volume calibrated by five inspiratory and expiratory strokes using a 3 L pump. Prior to determination of VO₂peak, a chest strap heart rate monitor was attached to participants' chests, with heart rate measured continuously throughout the test (Polar F1, Polar, Finland). The cycle ergometer (Wattbike Pro, Wattbike, UK) was adjusted to manufacturer's guidance. Saddle height was adjusted relative to the crank position and the foot was secured to a pedal with straps with participants' knee at almost full extension (~170°).

Participants mounted the cycle ergometer, and a rubber face mask was fitted (Hans Rudolph Inc, USA), which was attached to the Cortex II Metalyser 3B-R2. VO₂ and VCO₂ were recorded continuously throughout the test. Participants completed a 3 min warm-up at an intensity equivalent to ~10% of PPO. Subsequently, participants cycled at increasing intensity with 25 W increments each min until they reached volitional exhaustion, with rating of perceived exertion (RPE; 0-10 scale; Borg [1998]) recorded in the last 10 s of each stage. Immediately following volitional exhaustion, participants had their index finger cleaned using a disinfectant wipe, and then a
lancet was used to lacerate the fingertip to obtain a blood sample for to measure blood lactate (Lactate Pro 2, Arkray, Japan). VO_{2peak} was confirmed when participants achieved a minimum of any four of the following criteria; VO_{2} plateau, RER ≥1.10, peak heart rate within 10 beats of age predicted maximum and [BLa] ≥8 mmol·L^{-1}, final RPE of ≥9.

**Cytokine array**

Cytokine concentrations were quantified in an aliquot of serum utilizing a chip array system (Cytokine array I, Evidence Investigator, Affinity Biolabs, UK) with a sandwich chemiluminescent immunoassay technique for epidermal growth factor (EGF), interleukins (IL-1α, -1β, -2, -4, -6, -8, -10), IFN-γ, MCP-1, TNFα, and VEGF. Method precision and lower/upper limits of sensitivity have been previously reported (Karuppasamy et al. 2011), and quality controls were performed by the manufacturer using three known concentrations for each cytokine.

**Exercise training**

Older participants attended two SIT sessions per week, 72 h apart, as our pilot work suggested older adults would be suitably recovered from SIT in this timeframe (Yasar et al. 2019). Participants avoided strenuous physical activity 24 h prior to SIT sessions whilst maintaining habitual physical activity according to self-reporting. Participants warmed up for a period of 3 min at a self-paced intensity by performing static running. Participants then performed three 20 s static sprints at an ‘all-out’ intensity, interspersed by 3 min self-paced recovery phases. Following the final sprint, a 3 min self-paced cool down was performed (Fig 2). During all sprints, participants were instructed to raise their feet to approximately knee height, with loud verbal encouragement throughout each sprint.
Fig 2 Schematic representation of the sprint interval session. Participants performed this session twice weekly for eight weeks.

Statistical Analysis

Following confirmation of normality by a D’Agostino & Pearson normality test, cytokine data were examined by one-way analysis of variance (ANOVA) or Kruskal-Wallis test as appropriate, with post hoc interrogation by Dunnett’s multiple comparison test (younger as comparison group). Descriptive statistics (younger vs older pre-training) and training effects (older group only) were examined by unpaired t-test or Mann Whitney test as appropriate. Fisher's exact test tested for dichotomous differences in whether a cytokine was above or below the minimum level of detection in the older and younger group. Relationships between variables were determined using Pearson’s product-moment correlation coefficient. Effect size for paired comparisons is reported as Cohen’s $d$, interpreted as trivial ($<0.20$), small ($\geq 0.20-0.49$), moderate ($\geq 0.50-0.79$), and large ($\geq 0.80$). Parametric data sets are summarised in text as mean and standard deviation (SD) whilst non-parametric are given as median (upper - lower quartile). Figures are presented as grouped dot plots, as recommended by Drummond and Vowler (2011). Alpha level was not set dichotomously as significant or non-significant as recommended by Hurlbert and colleagues (2019). All figures were generated in GraphPad (5.02, GraphPad).
RESULTS

Anthropometric and performance measures

At baseline, older men did not differ from younger men in terms of body mass \((p = 0.635, \text{Cohen's } d = 0.13)\), BMI \((p = 0.070, \text{Cohen's } d = 0.04)\), resting heart rate BMI \((p = 0.517, \text{Cohen's } d = 0.30)\), systolic blood pressure BMI \((p = 0.803, \text{Cohen's } d = 0.11)\), diastolic blood pressure BMI \((p = 0.896, \text{Cohen's } d = 0.06)\), or BMI \((p = 0.070, \text{Cohen's } d = 0.04)\). However, older men did exhibit a lower \(V_{\text{O2}}\text{peak} \ (p = 0.004, \text{Cohen's } d = 1.48)\) and PPO \((p < 0.001, \text{Cohen's } d = 4.05)\) (Table 1). The SIT intervention produced a trivial increase in older participants' BMI \((p = 0.039, \text{Cohen's } d = 0.12)\), a small increase in \(V_{\text{O2}}\text{peak} \ (p = 0.268, \text{Cohen's } d = 0.23)\), a small increase in PPO \((p = 0.072, \text{Cohen's } d = 0.35)\), a small decrease in resting heart rate \((p = 0.263, \text{Cohen's } d = 0.40)\) a trivial reduction in systolic blood pressure \((p = 0.701, \text{Cohen's } d = 0.13)\), and a small decrease in diastolic blood pressure \((p = 0.347, \text{Cohen's } d = 0.33)\).

Table 1: Participant anthropometric and performance parameters at baseline (young and older pre-training) and following sprint interval training (SIT; older post-training). Values given as mean (SD).
SIT = sprint interval training, BMI = body mass index, VO$_{2peak}$ = peak oxygen uptake, PPO = peak power output. * young different to older at the p < 0.05 level, † older pre-SIT different to older post-SIT at the p < 0.05 level.

Cytokines

Of the 12 cytokines measured by chip array, IL-1a, IL-1b, IL-2, IL-4, IL-6, IL-10, IFN-γ and TNFα were frequently below the limit of detection of array methodology and thus concentrations are not further reported. For clarity, we report on cytokines whereby > 75% of samples returned with values above the lower limit of detection. Ordinal analysis of the data suggests that pro-inflammatory cytokines IL-1a, IL-1b, IL-6 were more frequently observed in the older cohort, whilst classically anti-inflammatory cytokines IL-2 and IL-10 were more often observed quantifiable in the younger cohort. However, Fisher's exact test revealed no differences between younger and older for the frequency of cytokines above or below the limit of detection (Table 2). Pro-inflammatory cytokines IL-8 and MCP-1, and growth factors VEGF and EGF were consistently detected and further described below.

Table 2: Cytokine marker state at baseline for young (n = 11) and older (n = 9). Markers were accepted if > 75% of samples returned concentrations > lower limit of detection. P values represent Fisher's exact test for whether the proportion of cytokine detected was different between the young and older group.

The effect of age and SIT on EGF, IL-8, VEGF and MCP-1, was compared by one-way (condition [younger, older pre-training, older post-training]) ANOVA. EGF showed an effect of condition ($p = 0.002$). The effect of condition was examined post hoc by Dunnett’s multiple comparison test, with the younger condition as the comparison. Older pre-training EGF was higher compared to the younger group ($p = 0.001$, Cohen’s $d = 1.64$; Fig 3), whilst the older post-training values were the same as the younger group ($p = 0.113$, Cohen’s $d = 1.07$; younger 60 [12] pg.mL$^{-1}$, older pre-training 142 [20] pg.mL$^{-1}$, older post-training 100 [12] pg.mL$^{-1}$). There was a large decrease in EGF in the older cohort as a result of SIT ($p = 0.101$, Cohen’s $d = 0.87$). There was no effect of group on remaining pro-inflammatory cytokines (IL-8, $p = 0.819$, Cohen’s $d = 0.28$; younger 9 [3] pg.mL$^{-1}$, older pre-training 8 [4] pg.mL$^{-1}$, older post-training 9 [4] pg.mL$^{-1}$; MCP-1, $p = 0.248$, Cohen’s $d = 0.68$; younger 274 [102] pg.mL$^{-1}$, older pre-training 341 [95] pg.mL$^{-1}$, older post-training 333 [88] pg.mL$^{-1}$) or VEGF ($p = 0.264$, Cohen’s $d = 0.72$; younger 117 [79] pg.mL$^{-1}$, older pre-training 191 [123] pg.mL$^{-1}$, older post-training 152 [80] pg.mL$^{-1}$; Fig 3b-d). When examining the magnitude of effect of training in the older group, there was a trivial effect of SIT on MCP-1 ($n = 9$; Cohen’s $d = 0.09$), and a small increase in IL-8 ($n = 7$; Cohen’s $d = 0.30$) and a small decrease in VEGF ($n = 9$; Cohen’s $d = 0.38$).
Fig 3 Cytokine concentrations of young, older pre- and older post-sprint interval training. a) EGF, b) IL-8, c) VEGF and d) MCP-1. Young shown in black circles, older shown in grey. Red horizontal lines indicate group means.

Relationships between baseline characteristics and circulating cytokines were examined by Pearson’s correlation matrix (Fig 4a). Age was strongly and negatively correlated with PPO and VO\textsubscript{2peak}, and moderately associated with EGF (Fig 4b). The EGF-PPO relationship was moderate (p = 0.004, r\textsuperscript{2} = 0.391; Fig 3b), and the EGF-VO\textsubscript{2peak} relationship was weak (p = 0.162, r\textsuperscript{2} = 0.106; Fig 4c).
Fig 4 Correlations between physiological and cytokine markers. a) Correlation matrix where values indicate r correlation coefficient and filled squares indicate where p < 0.05. Shading indicates strength of relationship (blue = positive, red = negative correlation). b) EGF (pg.mL⁻¹) as a function of PPO (W), C) EGF (pg.mL⁻¹) as a
function of VO$_{2 \text{peak}}$ (mL.kg.min$^{-1}$). For both b) and c), linear correlation indicated by red line, 95% confidence indicated by red dashed lines. Grey circles indicate older, black indicates younger.

DISCUSSION

The primary findings from the present study were 1) baseline EGF was greater in trained older men compared to younger participants, 2) there was no baseline differences in most (IL-1a, IL-1b, IL-2, IL-6, IL-8, IFN-γ, MCP-1, and TNFα) pro-inflammatory cytokines between trained older men and trained younger men, and 3) we make the novel observation that EGF was reduced to levels of younger men by a novel 8 week SIT intervention in trained older men.

Of the cytokines measured in the present work, only EGF was different between younger and older at baseline. EGF has a well understood action via the activation of the EGF receptor which is linked to inflammatory responses in terms of wound healing in mouse model keratinocytes, cellular proliferation, chronic kidney disease and tumorigenesis in humans, all of which are negative outcomes of ageing (Choi et al. 2018; Kasza 2013; Rayego-Mateos et al. 2018). However, data presented here should not be read as support of EGF as an activity-independent marker of biological age, as the addition of a novel exercise stimulus reduced EGF concentration in older participants. Indeed, it has been previously shown that overweight sedentary individuals possess lower plasma EGF compared to normal weight controls (Accattato et al. 2017). What physiological effect these alterations in EGF have on healthspan and lifespan can only be speculated at with the data presented here, but it is interesting to observe that a gain-of-function mutation in the EGF receptor promotes longevity in the model organism C. elegans, whilst loss-of-function mutations negatively affect longevity (Iwasa et al. 2010; Rongo 2011; Siddiqui et al. 2012).

We demonstrated 8 weeks of SIT reduced EGF in SIT-naïve but aerobically trained older men. We are unaware of other studies that investigate the effect of exercise training (i.e. >1 month) on EGF in older men. However, Accattato et al. (2017) established a single bout of endurance exercise (20 min run at 70% VO$_{2 \text{peak}}$) acutely suppresses EGF in younger individuals, yet resistance training has been shown to acutely increase EGF in healthy trained men (Diaz-Castro et al. 2020). Thus, it is clear the type of exercise (resistance vs endurance) influences EGF response after a period of training as recent studies in C2C12 myotubes have shown that EGF
receptor inhibition promotes a slow twitch (oxidative) over a fast-twitch muscle phenotype (Ciano et al., 2019).

Thus, after resistance training, an increase in EGF would be associated with an increase in muscle protein synthesis and hypertrophy whereas a decrease in EGF after endurance exercise is associated with oxidative adaptation. The clinical significance of these changes in EGF following exercise training is unclear however. Whilst greater EGF receptor prevalence is associated with multiple cancer types (Fisher et al., 2018; Gao et al., 2016; Tokunaga et al., 1995), cardiovascular disease (Makki et al., 2013), and in vitro EGF has been shown to influence cellular proliferation and differentiation rates (included in C2C12 myocytes [Ciano et al., 2019]), it is difficult to speculate concerning the biological role that post-SIT EGF suppression exerts in older men here.

Ageing is associated with a fast-to-slow muscle fibre type shift (Brunner et al. 2007; Deschenes 2004), as is chronic endurance training (Hawley et al. 2014), and this observation is maintained in lifelong endurance trained older individuals (Dubé et al. 2016). In a cohort of both healthy controls and chronic obstructive pulmonary disease patients, greater muscle EGF messenger ribonucleic acid (mRNA) expression was associated with fewer slow twitch muscle fibres and lower VO\textsubscript{2peak} (Ciano et al. 2019). Interestingly, our data suggest lifelong endurance training into older age is associated with higher EGF expression than younger adults, yet a relatively high VO\textsubscript{2peak}. The reasonably expected large percentage of slow twitch fibre type expression in our trained older participants may correlate with higher EGF expression, and the introduction of a ‘fast twitch’ promoting training stimulus could thus be speculated to induce the witnessed depression in circulating EGF, yet muscle biopsies would be required to confirm the fibre type shift.

Ageing is associated with an increased basal expression of circulating pro-inflammatory cytokines (Michaud et al. 2013). A recent meta-analysis concluded that chronic (at least 4 weeks) aerobic exercise in middle aged and older individuals decreased pro-inflammatory markers TNF\textalpha and IL-6 (Zheng et al. 2019). In addition, low physical activity levels and high sitting time increase overall risk of death from inflammation-related chronic disorders in people aged >60 years (Cabanas-Sanchez et al. 2018). In line with this, our results demonstrate that aerobically trained older men possess low circulating concentrations of several pro-inflammatory cytokines. Our data are thus in line with the hypothesis that basal inflammation seen in older individuals may be partly inactivity-induced, and not a result of chronological ageing per se. This is supported by the fact that several of
the cytokines reported here were below assay limits of detection, our participants did not show the elevated systemic inflammation typically seen in inactive older populations.

VEGF is a potent angiogenetic factor (Apte et al. 2019) and is essential for exercise-induced angiogenesis and subsequent improvements in performance (Wagner et al. 2006). In younger adults, resting VEGF was not changed following a HIIT intervention of 6 weeks (Żebrowska et al. 2019). VEGF positively associates with age in adults (Ruggiero et al. 2011) and has previously been reported to be increased in sedentary older individuals relative to lifelong exercisers, and further increased in sedentary individuals by 6 weeks of HIIT (Grace et al. 2015). We see no difference either in younger vs older trained individuals, or any pre-to-post training effect in our older population. Thus, any effects of ageing on circulated VEGF may be negated by lifelong exercise behaviour. In a similar manner MCP-1 positivity associates with age in mice and is elevated in older frail individuals relative to non-frail age matched controls (Yousefzadeh et al. 2018). As MCP-1 was not elevated in our cohort of trained older individuals relative to our younger population, this provides further support of the use of MCP-1 and VEGF as a marker of biological age, however, the addition of an inactive ageing control group to our model is needed to confirm this.

Some limitations to our study design should be acknowledged. We specifically sought to examine trained older individuals, comparing them to trained younger adults to remove any effect of inactivity on ageing. However, the addition of an inactive older group would have been a useful addition to confirm inactivity-associated ageing changes in pro-inflammatory cytokines and growth factors that others have reported. Likewise, a young training group would have provided insight as to whether they possess more plasticity with regards to serum cytokine concentrations. Additionally, this study did not include women and therefore findings cannot be extrapolated to women. Having multiple cytokine markers below useful limits of detection was a methodological weakness of the approach that we have utilised here, and future studies will need to consider the use of high-sensitivity biochip cytokine arrays, individual ELISA per marker, or the use of multiplex ELISA techniques, however, these methodological approaches are associated with greater resource commitments. Additionally, the present study did not verify objectively measured physical activity of participants during the study. Instead, the present study relied on self-reporting, which is subject to self-reporting bias.
In conclusion, here we make novel observations on the state of circulating pro- and anti-inflammatory markers in trained older individuals. EGF was greater in endurance trained older individuals compared to younger men, however, the addition of a novel SIT intervention in older men can shift circulating EGF towards trained younger concentrations. As EGF has previously been associated with longevity in *C. elegans*, the manipulative effect of SIT on EGF in healthy ageing in the human may be of further interest.

**Declarations**

**Funding**

Funding was provided by institutions employing the authors.

**Conflict of interests**

We declare no conflict of interest or competing interests.

**Ethical approval**

Ethical approval was obtained for this study and all participants provided informed consent. All authors have read the manuscript and consent for this work to be published. Data can be made available on request. Code details are not applicable within this manuscript, but all software details are given.

**Authors’ contributions are given according to the CRediT taxonomy:**
