ABSTRACT

1. Extensive and dense macroalgal fields can compromise the ecosystem function of habitat mosaics on reefs due to their limiting effect on patch connectivity. Macroalgae can maintain and increase their dominance with effective self-reinforcing feedback mechanisms. For instance, macroalgae can form dense beds, suppressing coral settlement and grazing by herbivores. This compromised ecosystem function can lead to major socio-economic and ecological changes.

2. Dense macroalgal beds were shaded with submerged shade sails of two sizes and changes to the underlying benthos and feeding rates of herbivorous fishes were recorded. The shade sails reduced the algae’s ability to photosynthesise by 29%. After six weeks, macroalgal cover reduced by 24% under small sails and by 51% under large sails. Small shade sails reduced turf algal growth by 23%, while large sails reduced growth by 82%.

3. Three months after removal of the shade sails, algal beds had almost completely regrown. During this regrowth period, herbivore bites taken from the experiment's substrates were recorded, with grazing impact reducing significantly with time.

4. This study is the first to achieve macroalgal reduction via the alteration of the light regime. While macroalgae regrew in this relatively short-term experiment, shading may be a viable reef management approach that aims to maximise habitat mosaics on coral reefs, particularly if used in combination with other intervention methods.

KEYWORDS

Reef, biomanipulation, habitat management, new techniques, algae, fish
Tropical coral reefs are changing globally, with corals reducing in cover and being replaced by other organisms such as algae (Hughes, 1994; Cheal et al., 2010; Graham et al., 2015). Coral-algal regime shifts can substantially alter the ecological, social, and economic value of reefs (Moberg & Folke, 1999; Hughes et al., 2010; Robinson et al., 2019), especially when systems become dominated by few weedy algal species of low complexity (Littler & Littler, 1988; Hughes, 1994; Mumby, 2009). With an increasing frequency of disturbances threatening corals (Hughes et al., 2018), future predictions of coral-dominated systems, and the ecosystem services they support, are uncertain (Williams & Graham, 2019; Woodhead et al., 2019). The changing compositions of reefs (Graham et al., 2014) may also give way to a mosaic of habitat patches, where multiple patch reef types form an interconnected tropical seascape (Nagelkerken et al., 2015; Harborne et al., 2016; Fulton et al., 2019). The mosaic can consist of habitat types such as corals, seagrass, and macroalgae, that each can benefit different communities or different life stages of individual species within those communities (e.g. fish) (Berkström et al., 2013; van Lier et al., 2018). Connectivity between habitat types is critical for functioning reef mosaics (Olds et al., 2018). Substantial reductions in fish diversity have been observed when the distance between coral patches was greater than 500 m for resident fish species (van Lier et al., 2018) or 750 m when considering transient foragers (Berkström et al., 2013). Further, reef mosaic integrity and overall reef ecosystem function can decrease as individual, homogeneous habitats extend and increase the space between patch habitats (Olds et al., 2018). In summary, if homogenous macroalgal patches expand and the distance between other habitat type patches, such as coral, becomes larger than their resident species’ home ranges, overall species diversity can decline. Therefore, patch connectivity should be considered in management in order to maximise the functioning of each patch (Fulton et al., 2019).

Conceptual models suggest that macroalgae can be very efficient at reinforcing their spatial dominance with feedback mechanisms (Mumby & Steneck, 2008; Nyström et al., 2012; van de Leemput et al., 2016). Feedbacks are cause-effect loops where one aspect (A) affects another (B) which in turn feeds favouring conditions back to the original aspect (A). Observational and experimental studies have
identified various macroalgal reinforcing feedbacks (Hoey & Bellwood, 2011; Dell, Longo & Hay, 2016; Johns et al., 2018; Loffler et al., 2018; Loffler & Hoey, 2018). For example, once stands of the common tropical macroalgal genus *Sargassum* reach a certain density (A), they suppress grazing by fish herbivores (B), and the reduction of feeding pressure then allows macroalgal fields to grow further (A) (Hoey & Bellwood, 2011). In addition, limited space in these fields prevents benthic settlement by other organisms such as corals (Dell, Longo & Hay, 2016), and can lead to the development of microbe aggregations that cause diseases in remaining corals (Smith et al., 2006). The result can be an ever-expanding homogeneous field of weedy macroalgae (Mumby, 2009) which can compromise reef mosaic connectivity (Berkström et al., 2013; van Lier et al., 2018).

In order to limit the extent of dense homogeneous macroalgal fields and maximise ecosystem function of mosaic-style habitats (Fulton et al., 2019), studies have investigated ways to reduce algal cover. Experiments that remove macroalgae manually, have had short lived success due to rapid regrowth likely from leftover algal attachment structures (holdfasts) (Tanner, 1995; McClanahan et al., 2001; Roff et al., 2015; Loffler et al., 2018; Loffler & Hoey, 2018). Following an unusually long period of overcast weather (42 days) in Kāne‘ohe Bay, Hawaii, a mass-macroalgal die-off occurred, likely caused by the lack of sufficient photosynthetically active radiation (PAR) (Stimson & Conklin, 2008). The macroalgae did not return for the 2 years of subsequent monitoring, suggesting that shading may be a feasible approach to weaken macroalgal feedbacks. Turf algae can present an additional problem because of their ability to rapidly colonise open settlement space under favourable environmental conditions (e.g. sufficient nutrient and light levels) (Littler & Littler, 1992). Turf algae can also prevent the settlement of other benthic organisms such as corals (Birrell et al., 2005), colonising open space rapidly and potentially impairing connectivity in relatively short time frames.

In this study an artificial shading experiment was established in a bay of Curieuse Island, Seychelles that was entirely dominated by dense macroalgal fields. The overarching objective was to create macroalgal free patches and attract herbivorous fish to these patches. Specifically, the following questions were formulated: 1) does a shading period of 42 days (6 weeks) result in a reduction of
2) do herbivorous fish graze more in patches of reduced macroalgal cover?

2. METHODS

2.1. Study site and organisms

This study was conducted from January until June 2018 at Anse Papaie (4.28°S, 55.73°E), Curieuse Island, Seychelles. The bay was chosen due to its continuous, thick macroalgal beds extending to relatively deep water (6 m at high tide) and its status as a marine park to minimise boat traffic. The dominance by macroalgae likely developed following the 1998 bleaching event, that led to many Seychelles reefs shifting dominance from corals to macroalgae (Graham et al., 2015). Prevailing winds in the inner Seychelles come from the north-west between December and March and start turning into south-easterly winds in late March, staying this way until October, followed by intense rainfalls and winds through November and December (M Belmont and V Amelie, Seychelles Meteorological Services). With Anse Papaie on the eastern side of Curieuse, the bay remains relatively wind-sheltered from late January until mid-March. Macroalgae overstorey in the bay are primarily Sargassum spp. with some Turbinaria spp. present, while the understorey is primarily Lobophora spp. and Dictyota spp. Sargassum often display strong seasonality in growth patterns around the world. Sargassum seasonality in the inner Seychelles appears to be tied to the prevailing seasonal winds and currents (Bijoux, 2013). Sargassum appear to senesce during the cloudy south-east wind period (from May to October) and regrow during the predominantly clear-sky north-west wind period (December to March). This drove the choice of experimental timing (January to June), during which skies are predominantly clear and Sargassum are not subjected to senescence but instead are in a regrowth phase.

2.2. Experimental setup

Submerged square-shaped shade sails (> 98 % UV-blockage certified according to Kookaburra Shade Sails, Sydney, Australia) of two sizes (4 m² & 9 m², five of each size) were built over continuous macroalgal cover and does the shade prevent turf algae from colonising the newly cleared space?; and
Each shade sail was mounted on four threaded steel rods (ø = 22 mm, length = 1.5 m), with the rods hammered 50 cm into the sediment to allow at least 1 m between the rod’s end and the water’s surface at low tide (to allow boat passage) and for the algae (~ 30 cm maximum height) not to touch the shade sails. Each sail had ~ 20 cm slack above and below the highest point of the rods to prevent ripping with the wave action. The shade sail structures were put in place on 28/01/2018 and they remained fixed for 42 days until deconstruction on 11/03/2018 to prevent shifting winds from disrupting the experiment. Control plots were constructed of solely steel rods (no shade sails) on the same reef. The total experimental setup included 16 plots (five 4 m² treatments, five 9 m² treatments, three 4 m² controls, three 9 m² controls) running in rows parallel to the shoreline, at a similar depth. Plots were separated to ensure there was no overlap in shade and control plots were 15 m from experimental plots. Altogether, the experiment covered roughly 450m².

### 2.3. Sampling and statistical analysis

All sampling was conducted using snorkel gear. HOBO pendant loggers were deployed to measure light intensity (in lux) underneath the sails (Fig. S2). The loggers were placed on PVC pipes (35 cm), keeping them above the macroalgal canopy and in the centre of each plot. Loggers were deployed in the first week of shading from 11:00 to 16:00 h and took light intensity readings every 10 min. This method was replicated in control plots.

#### 2.3.1. Macroalgal cover

Planar view photographs of treatment and control plots were taken immediately before installing and immediately after taking down the sails. The process was repeated monthly following sail removal, with the last picture taken on the 11/06/2018, 3 months following shading. These pictures were compared using “Coral Point Count with Excel extensions (CPCe)” (Kohler & Gill, 2006) to obtain the change in percent macroalgal cover over time.

To statistically investigate the effects of sail size and time (fixed effects), generalised linear mixed models (GLMM) were fitted to macroalgae cover using the lme4-package in R (Bates et al., 2015). The model was fitted with ‘plot’ nested in ‘treatment’ as a random effect to address dependencies.
induced by repeated measures through time. To avoid having a percentage-based response variable, macroalgae cover was used as a binary response variable (1 = macroalgae, 0 = no macroalgae) with each randomly allocated point in the HD-photographs being one observation (n = 50 per photo, n = 4000 in total) and fitted it with a GLMM with a binomial distribution.

### 2.3.2. Settlement blocks: turf algal growth potential

To simulate benthic regrowth, one settlement block (10 x 10 cm, made from marine cement, mounted on an individual steel rod to raise the block above the macroalgal canopy) was deployed in the centre of each treatment and control plot when the experiment started. The cement blocks remained under the sails for the entire time of active shading. The blocks were collected with the shade sail removal and analysed for algae cover using photographs and CPCe (Kohler & Gill, 2006). A GLMM was fitted with sail size and time as fixed effects and plot nested in treatment as a random effect. The same binary allocation as for macroalgal cover data (1 = turf algae, 0 = no turf algae) was done for the settlement blocks data (n = 30 per photo, n = 270 in total) and a binomial GLMM was fitted to the data.

### 2.3.3. Photosynthetic efficiency

Every week during active shading and one additional week after, three random basal blades from different plants of each plot were collected from 09:00-10:00 am, at medium to high tide (~ 40 cm difference). These blades were placed in a black, optically opaque bag and, within a maximum of 30 min, taken from the field site to a wet laboratory, where the same light conditions were kept for the duration of the experiment. Each blade was analysed individually with a Junior pulse-amplitude modulation (PAM) chlorophyll fluorometer (Walz, Erlangen-Eltersdorf, Germany) using light curves that applied photo fluence rates of 120, 192, 273, 414, 574, 903, 1341, and 2010 µmol PAR m\(^{-2}\) s\(^{-1}\) consecutively, with 1 min intervals in between. The interval time was sufficient to allow a return to a steady state following saturation pulses. The values obtained from measuring three blades were averaged per plot. The light curves were used to obtain the effective photochemical quantum yield \(Y(\text{II})_{\text{max}} = \Delta F / Fm'\) as a representative measurement of photosynthetic efficiency per plot per week. A linear mixed model (LMM) was fitted to photosynthetic efficiency data with sail size and time as the factors.
fixed effects and plot as a random effect. The photosynthetic efficiency (Y(II)) data met the
assumptions of the LMM as an untransformed response variable with Y(II) recordings averaged for
each plot (n = 112).

2.3.4. Herbivore feeding following experimental deconstruction

After removal of the shade sails, the plots were monitored in March, April, and May 2018 with six
digital video cameras (GoPro Hero 4). To quantify the herbivore feeding impact per m² on the
experimental plots, the cameras were deployed on PVC-arms which were mounted on one of the
corner steel rods (Fig. S1) of each plot, and filmed for 4 hours between 10:00 and 14:00. A 1-hour film
segment situated at least 30 min after deployment and at least 30 min before the end of filming was
analysed. Each bite taken by an individual fish and respective species was recorded. An LMM to
herbivore bite data with sail size and time as fixed effects and plot nested in treatment as a random
effect was fitted. The response variable of herbivore bites per m² was log₁₀-transformed with every
fish being an individual observation (n = 3859).

Models were not or only weakly biased by collinearity (Zuur, Ieno & Elphick, 2010). The residual
plots of all four models suggested good model fits. Pair-wise comparison Tukey post-hoc tests were
conducted for the four models using the emmeans-package in R (Lenth et al., 2019). All analyses were
conducted in R version 3.5.3 (R-Core-Team, 2019). R-scripts and data are provided at an open source

3. RESULTS

3.1. Macroalgal cover

Macroalgal cover significantly declined from before shading (January) to after shading (March) on
small plots of 4 m² (Fig. 1, 23.6 % reduction January vs. March shaded 4 m²: Tukey pair-wise
comparison z-Δ₄ = 4.72, p = 0.003) and large plots of 9 m² (51.2 % reduction January vs. March
shaded 9 m²: z-Δ₉ = 10.25 p < 0.001), while the controls showed non-significant increases in
macroalgal cover (3.33 % increase January vs. March controls 4 m²: z-Δ₄ = -0.52, p = 1; 2.67 %
increase January vs. March controls 9 m²: $z_{\Delta 9} = -0.41, p = 1$). Macroalgal cover returned following
shade removal with significant differences still present after 2 months (12 % reduction January vs.
May shaded 4 m²: $z_{\Delta 4} = 4.24, p = 0.012$; 20.4 % reduction January vs. May shaded 9 m²: $z_{\Delta 9} = 4.08,
p = 0.02$). Three months after shade removal, both plot sizes had returned to similar macroalgal cover
compared to before shading (1.2 % reduction January vs. June shaded 4 m²: $z_{\Delta 4} = 0.24, p = 1$; 7.6 %
reduction January vs. June shaded 9 m²: $z_{\Delta 9} = 1.52, p = 0.99$). Controls showed little change
throughout the experiment.

### 3.2. Settlement blocks: turf algal growth potential

Turf algae covered most of the area on the previously clear settlement blocks in control plots (Fig. 2).
In the small shade sail plots, turf algae covered on average 67.8 % (23.37 % reduction control vs.
shaded 4 m² tiles: $z_{\Delta 4} = 2.7, p = 0.02$), while in the larger shade plots turf only covered 8.89 % (81.9
% reduction control vs. shaded 9 m² tiles: $z_{\Delta 9} = 7.1, p < 0.001$). The rest of the cement block surface
remained bare, apart from negligible bryozoan cover.

### 3.3. Photosynthetic efficiency

The photochemical quantum yield of photosystem II (Y(II)) of macroalgae in shaded conditions
changed over the duration of the experiment, with noticeable decreases occurring in week 5 (Fig. 3).
The diversion from baseline measurements taken before the experiment (week 1) were not significant
throughout the experiment for shaded macroalgae in small plots (12 % reduction week 1 vs. week 5: $t_{\Delta 4} = 2.6, p = 0.51$). For large plots on the other hand, the depression in photosynthetic efficiency for
shaded macroalgae in week 5 was significant (29 % reduction week 1 vs. week 5: $t_{\Delta 9} = 5.8, p < 0.001$) and remained significant until week 6 (18 % reduction week 1 vs. week 6: $t_{\Delta 9} = 0.1, p = 0.04$).
One week after removal of the shade sails (week 7), photosynthetic efficiency was not significantly
different from values in week 1 for both plot sizes (small: 6 % reduction week 1 vs. week 7: $t_{\Delta 4} = 1.6,
p = 0.987$; large: 9 % reduction week 1 vs. week 7: $t_{\Delta 9} = 2.65, p = 0.5$). Y(II) of macroalgae in control
plots did not change significantly throughout the experiment.

### 3.4. Herbivore feeding following shade sail removal

9
Regardless of plot size or herbivore functional group, bites taken from plots reduced with time following experiment deconstruction (Fig. 4). Browser and grazer feeding did not differ significantly between control plots and plots that were previously shaded for small (control vs. shaded 4 m²: $z_{Δ_4} = -1.415$, $p = 0.96$) or large plot sizes (control vs. shaded 9 m²: $z_{Δ_9} = -0.732$, $p = 0.99$). However, there were significant differences between control and previously shaded plots in scraper feeding on large plots one month after shade-sail removal (control vs. shaded 9 m² for scrapers in April: $z_{Δ_9} = -4.78$, $p = 0.001$) which had subsided two months after removal (control vs. shaded 9 m² for scrapers in May: $z_{Δ_9} = -1.602$, $p = 0.99$).

### 4. DISCUSSION

This study demonstrates that macroalgal reduction can be accomplished using submerged shade sails within 42 days or less, and that reduction scales with shade sail size. Shading also limits turf algal regrowth, potentially making space available to other benthic settlers. Once the shade sails were removed, a significant increase in herbivore grazing was not detected in the experimental plots, which indicates that the macroalga-reinforcing feedback was not sufficiently weakened. The algal reduction method presented here may be used in a reef management approach that pursues the maximisation of ecosystem services drawn from a habitat mosaic reefscape.

The prolonged shading likely hindered the algae’s metabolic ability to a point where net-positive photosynthesis could not be sustained (Littler & Littler, 1992; Shiu & Lee, 2005; Teichberg, Fricke & Bischof, 2013). Initially, *Sargassum* was able to acclimatise to the light regime changes and did not show a loss of photosynthetic efficiency for four weeks, although a darkening in blade colouration was visible from week 2 (pers. obs.). The initial acclimatisation to a darker light regime could be possible because the plant increases their light-harvesting pigment content to maximise photosynthesis when PAR is limiting (Littler, Littler & Lapointe, 1988; Littler & Littler, 1992; Abal et al., 1994; Lirman & Biber, 2005). This photoadaptation in macroalgae is likely achieved by diverting energy away from growth and towards maximising photosynthesis, as reported for other tropical marine macroalgae (e.g. *Halimeda*) (Littler, Littler & Lapointe, 1988; Teichberg, Fricke & Bischof, 2013). At week 5, the PAR
that *Sargassum* plants were able to harvest in shaded conditions proved insufficient to sustain photosynthesis levels required to prevent biomass loss. It is possible that reactive metabolic by-products, such as oxygen radicals, caused oxidative damage to the plant photosystems (Shiu & Lee, 2005). In addition, the constant variations in light-intensity reaching the algae induced by movement of the shade sails in wave action may have proven challenging to photoadaptation and the sustenance of net-positive photosynthesis (Taylor & Long, 2017). In some cases, intermittent light regimes in seaweed canopies have been shown to stimulate growth and result in higher productivity within canopy environments (Bennett et al., 2015), however, the evidence presented here suggests the opposite.

The decrease in photosynthetic efficiency likely resulted in the observed discolouration of the plants and eventually led to a disintegration of the algal thalli. This may have affected the palatability of the plants to herbivores. The palatability of macroalgae to herbivores seems to partly depend on the carbon-to-nitrogen ratio (C:N-ratio) within the plant tissue (Vergés et al., 2011). Lower C:N-ratios have been experimentally associated with increased herbivore palatability (Barile, Lapointe & Capo, 2004; Van Alstyne, Pelletreau & Kirby, 2009). Given that changing light-regimes affect plants’ photosynthesis and therefore their ability to maintain a C:N-ratio (Teichberg, Fricke & Bischof, 2013), this ratio can be expected to have changed in this experiment. Unfortunately, palatability using C:N-ratios could not be quantified in this experiment due to the lack of necessary equipment on Curieuse (e.g. -80°C-freezer).

In addition to the decrease in photosynthetic efficiency, herbivorous fish, which are abundant in the area (Robinson et al., 2019), could have grazed on the experimental algae and thus contributed to the reduction in macroalgal cover observed. While grazing footage of herbivorous fish was obtained after the removal of the shade sails, this could not be done while the shade sails were in place. A camera angle that could balance a view far above the macroalgal canopy (~ 30 cm maximum height) to see the substrate clear enough to identify the fish grazing and still be below the lowest point of the shade sail (sail was ~ 60 cm above the substrate) could not be set up. In order to obtain grazing footage while the shade sails were in place, the shading structures would have needed to be built higher above the
substrate, which then would have reduced the shading efficiency and the ability for boats to pass overhead. In addition, the HD-photographs enabled macroalgae to be identified to genus level, which was more than 90% *Sargassum* cover in our experiment. Therefore, the majority of the results relate to *Sargassum*. However, since the photographs were taken from planar view, this only represents the overstorey and inferences cannot be made about the understorey that might have been growing under the *Sargassum* canopy. *Lobophora* algae for instance can grow in the understorey of other algae (Roff et al.; 2015) and could have been affected been the preferred food source of some herbivores.

The macroalgae-reinforcing feedback was not weakened sufficiently, as the experimental plots with reduced macroalgal cover after shading did not show significantly higher feeding rates by herbivorous fish compared to the controls. The macroalgae regrew to roughly pre-experimental cover levels within 3 months. After deconstruction on the 11th of March 2018, herbivorous fishes remained in the plot areas for the first post-experimental month and grazed more intensely on both the shaded and control plots in March, before declining gradually. There are some plausible mechanisms for this. Firstly, the experimental design may simply have lacked statistical power, resulting in the large variability in the dataset. As mentioned, browsing herbivores may have been involved in the macroalgal reduction while the shading structures were in place. Their involvement after shade sail removal may not have been detectable by the experimental setup because with returning light, the macroalgae may have been able to re-establish their unpalatability through secondary metabolites. Scraping parrotfish on the other hand seemed to preferentially target large shaded plots in the March surveys. Since scraping parrotfish target turf algae and microbial communities in dead reef structures (Bellwood & Choat, 1990; Streelman et al., 2002; Bonaldo, Hoey & Bellwood, 2014; Clements et al., 2017), and the experiment cleared most macroalgae and exposed more open settlement space that could readily colonised after sail removal, resources for scrapers would be abundant in the experimental plots. Another explanation could be that herbivores may have become used to feeding around the structures, such that the intense grazing in March was a lag effect of the structural attraction, as reef fish can be attracted by structures similar to ours (Kerry & Bellwood, 2015). As distance between control and experimental plots is likely incorporated within fish foraging ranges, declines in feeding rates occurring gradually for both plot types may be expected. Future studies could employ alternative control structures to help reduce
the uncertainty in the above-described issue. This could include controls without any structure, not
even rods, in addition to controls with non-shading, transparent sails to account for the movement of
the sail and for potential fish scaring.

The observed regrowth rates of 3 months roughly match those of a previous study that also used
percent cover as a metric - *Sargassum*: 2 months (McClanahan et al., 2001), *S. herporhizum*: < 1
month, *S. sinicola*: > 3 months (McCourt, 1985). However, macroalgal biomass, and associated
feedback mechanisms, may take longer to re-establish (Loffler & Hoey, 2018). The six-week shading
method led to a significant reduction of macroalgal cover and we can suggest a combination of
possible reduction mechanisms. An interesting question remains as to whether the algae regrew
because of low herbivory, or the herbivores moved because the macroalgal feedbacks were not
sufficiently weakened. Along our previous reasoning, we believe the latter. It could be that with the
removal of the shade sails, the return to a normal light regime allowed the macroalgae to again
reinforce their unpalatability to herbivores which then led to herbivore disengagement and regain of
strength in the self-reinforcing feedback.

While other studies have reduced macroalgal cover by manual removal (McClanahan et al., 2001;
Loffler et al., 2018; Loffler & Hoey, 2018), the present study is the first to do so via shading for a
limited time frame. The time to physically keep the shade sails in place was restricted by the increase
in wave action. While this study confirmed that localised macroalgal reduction can be achieved within
42 days as indicated by an observational study (Stimson & Conklin, 2008), clearing the plot of
holdfasts could not be achieved. Given the resistant nature of the algae’s holdfasts (Ceccarelli et al.,
2018), we think that it would be interesting to see whether a longer shading time would result in a
reduction of holdfasts, since most of the observed macroalgal regrowth following shade sail removal
has likely come from leftover holdfasts (Loffler et al., 2018). Alternatively, since the shorter six-week
time frame might be particularly interesting to management as the longer time frame might not be a
realistic management tool (Ceccarelli et al., 2018), perhaps a combination with other intervention
methods, e.g. shading areas manually cleared of holdfasts, could be of greater management use. Based
on the photographs before and after shading, we do believe holdfast densities decreased.
Notably, the efficiency of macroalgal reduction did scale with shade sail size. Future studies could consider using significantly larger sails to maximise macroalgal reduction and perhaps enable them to record a clearing of holdfasts as well. Scientifically, it would be interesting to see whether the increasing trend of macroalgal reduction with sail size continues. From a management perspective, we do not believe that shade sails much larger than 9 m² would be practical. The 9 m² shade sails did present a slight loss in tension towards the end of our experiment. This could result in the centre of the shade sail dragging on the substrate and result in abrasion of macroalgae and other benthic organisms. While the loss in tension in this experiment was not drastic enough for sails to make contact with the substrate or the algae, shade sails larger than 9 m² may well present this problem. In addition, coral reef managers may find the short 6-week time frame and relatively small 9 m² shade sail size particularly appealing. As suggested throughout this manuscript, this method does hold most potential to management pursuing a mosaic reefscape approach.

That other benthic settlers (e.g. corals) can grow on the cleared settlement space could not be demonstrated because of the limited experimental period. Based on coral settlement studies that monitored coral settlement for 5 - 29 months (Babcock & Mundy, 1996; Mangubhai, Harrison & Obura, 2007; Yadav et al., 2016), we suggest that future studies find sites and/or shading structures that allow for a longer period of uninterrupted shading to be able to observe a potential increase in coral recruits.

This study tested a novel method of macroalgal reduction that could be used and further developed for localised intervention approaches that aim to manage productive reefs made up of a mosaic of interconnected habitat patches. We recognise the importance of natural macroalgal reefs (Fulton et al., 2019) and that macroalgae will increasingly be a part of ecological (Nagelkerken et al., 2015; Harborne et al., 2016) and socio-economic reef potential (Robinson et al., 2019). But since self-reinforcing feedbacks can lead macroalgae to dominate continuous stretches of reef and thereby expand beyond connectivity thresholds that are critical for a productive mosaic, reef management needs ways to address macroalgal expansion. While the method presented here did not interrupt macroalgae-reinforcing feedbacks to the point where feeding rates by herbivorous fish significantly
increase, it weakened them so that macroalgal cover could be significantly reduced. The presented method reduced macroalgal cover by altering the light regime and may be useful as part of a suite of intervention strategies, particularly to shade areas cleared of holdfasts, and perhaps aiding coral recruitment on newly provided settlement substrates.

FIGURES LEGENDS

Figure 1. Macroalgal cover (in %) changes observed monthly in shaded plots and unshaded control plots of different sizes (4 m² & 9 m²) over the active shading period (grey area) and post-removal/algal regrowth period (white area); central line: mean, boxplot boundaries: interquartile range, outside dot: value is > 1.5 times and < 3 times the interquartile range beyond either end of the box, whiskers: ± standard error.
Figure 2. Turf algae cover (in %) observed on settlement blocks that were deployed in shaded plots of different sizes (4 m² & 9 m²) and unshaded control plots and collected following deconstruction of the experiment in March 2019; central line: mean, boxplot boundaries: interquartile range, whiskers: ± standard error.

Figure 3. Photochemical quantum yield of photosystem II (Y(II)) of experimental Sargassum macroalgae throughout weeks of active shading (grey area) and one week after (white area) in shaded plots of different sizes (4 m² & 9 m²) and unshaded control plots; central line: mean, boxplot boundaries: interquartile range, outside dot: value is > 1.5 times and < 3 times the interquartile range beyond either end of the box, whiskers: ± standard error.

Figure 4. Bites per m² taken by three herbivore fish functional groups (browsers, grazers, scrapers) from shaded and control plots of different sizes (4 m² and 9 m²) in one-hour video samples; recordings were taken monthly following shade sail deconstruction, error bars: ± standard error.

SUPPLEMENTARY MATERIAL

Figure S1. Shading structure atop macroalgal field (top) and photographs of one experimental patch at time intervals before and after shading.

Figure S2. HOBO pendant logger readings of light intensity (in lux) below the small and large shade sails as well as control plots during first week of shading from 11:00-16:00 h.

Table S1: Species list of herbivore species observed during the feeding assays experiment

- Acanthurus grammoptilus
- Acanthurus triostegus
- Ctenochaetus striatus
- Leptoscarus vaigiensis
- Platax orbicularis
- Scarus atrilunula
- Scarus ghobban
- Scarus prasiognathos
| 408  | Scarus rubroviolaceus  |
| 409  | Scarus scaber         |
| 410  | Scarus sordidus       |
| 411  | Siganus puellus       |
| 412  | Siganus sutor         |
| 413  | Zebrasoma scopas      |
