Abstract: Global synchronisation of environmental change in terrestrial successions in deep-time is challenging due to the paucity of dating methods, a case also applicable to the Middle to Upper Triassic Mercia Mudstone Group in Britain. Using coastal cliff sections, magnetostratigraphy was evaluated at 263 horizons, defining 53 magnetozones. Magnetozones from the lower 140 m of the group demonstrate correspondence to those from the mid Ladinian to early Carnian polarity timescale, dating which is compatible with magnetostratigraphy from the underlying Sherwood Sandstone Group. Magnetostratigraphy of the Dunscombe Mudstone Formation, and associated palynological data, suggest a late Carnian to earliest Norian age, and a dramatically lower accumulation rate than adjacent formations. The polarity record demonstrates coeval flooding events, evaporite deposits and intervals of sand supply between the Wessex Basin and the Central European Basin in the Carnian. This is the result of linked climatic and eustatic changes between these separate basins, related to aeolian dust supply and the shrinkage of hyper-arid source regions for the fines. Magnetostratigraphy from the Branscombe Mudstone and Blue Anchor formations demonstrates their Norian and early Rhaetian age. These and other data suggest an alternative synchronization of marine and non-marine polarity records for the Norian polarity timescale.
198 words

Supplementary material: Section details and detailed logs of the sampled sections and inferred sequence boundaries, magnetic mineralogy data, demagnetisation behaviour and mean directions, summary of virtual geomagnetic pole data and a comparison to other European poles, construction of other composite reference sections and revised polarity

32   scales. Excel sheet of magnetic data statistically evaluated correlation models, and age

33   models.

34

35 Accurate and precise dating of sediment successions is the cornerstone of global

36 understanding of many past environmental changes in deep time. It is particularly challenging

37 merging datasets from terrestrial successions into such understanding, because of the

38 common lack of detailed, accurate and precise biostratigraphies. In Europe the Middle and

39 Late Triassic contains rather contrasting intervals of environmental change. The Middle

40 Triassic saw the marine flooding of the Central European Basin (CEB) from the Palaeotethys

41 Sea, through gateways on its southern borders (McKie 2017). Faunal and floral turnovers

42 were low during the Middle Triassic (Brayard et al. 2009; Song et al. 2018). During the

43 Carnian, the start of the Late Triassic, major environmental changes are linked to a northern-

44 hemisphere-focused humid episode (Ruffell et al. 2016), which is associated with the

45 diversification of the dinosaurs (Bernardi et al. 2018). The transition into the Norian

46 witnessed major turnovers in marine biota (Dal Corso et al. 2020), linked to significant

47 fluctuations in sea-water temperature, which later in the Norian witnessed rising temperatures

48 and a climax in reef-building in the Palaeotethys (Sun et al. 2020).

49 In Britain the Mercia Mudstone Group (MMG) occupies part of the Middle (Ladinian

50 Stage) and most of the Upper Triassic (Carnian to Rhaetian stages), which is ~36 Myr in

51 duration, representing 72% of the Triassic (Ogg et al. 2020). However, the chronostratigraphy

52 of the MMG is poorly understood, so synchronisation of environmental signals encoded in

53 these red-bed sediments has remained elusive. The type section of the MMG is on the Devon

54 coast and lies within the Dorset and East Devon Coast World Heritage Site (Gallois 2019).

55 The MMG sections on the Devon coast are among the best exposed and accessible Middle

56 and Upper Triassic sedimentary rocks in Europe. The MMG contains palynological

57 assemblages recorded from two intervals, which allow a loose biostratigraphic age

58 assignment to parts of the Carnian and Rhaetian (Warrington 1997; Hounslow et al. 2004;

59 Baranyi et al. 2019). Other intervals are barren, hence the detailed chronostratigraphy of the

60 remainder of the MMG is unknown. On the Devon coast the MMG rests on the Middle

61 Triassic Otter Sandstone Formation (Fm), with the age of its upper part based on

62 magnetostratigraphy and vertebrate fossils, thought to be Anisian in age (Benton et al. 1994;

63 Benton 1997; Hounslow and McIntosh 2003). The current work addresses the age of the

64 MMG using magnetostratigraphy, which allows the importation of chronostratigraphy by

65 correlation with conodont and ammonoid dated successions elsewhere, that contain a linked

66 magnetostratigraphy. This provides better insight into synchronisation of environmental

67 changes with elsewhere in Europe.

68   The MMG was also important in the early development of palaeomagnetism, with

69   geomagnetic reversals first detected in this unit in the pioneering study of Clegg et al. (1954).

70   Expanding on preliminary work of Creer et al. (1954), the details of the first

71   magnetostratigraphy from Triassic age sediments was by Creer (1959) from a 52 m section

72   across the Otter Sandstone Fm - MMG boundary east of Sidmouth, in which three

73   magnetozones were identified. Also pioneering was the use of alternating field tumbling

74   demagnetisation on sediments which was later followed by a pioneering study using low-

75   temperature methods to characterise the magnetic mineralogy of red beds (Creer 1961).

76   Currently, the Middle and Late Triassic geomagnetic polarity timescale (GPTS) is

77   reasonably well understood allowing international chronostratigraphic correlations to be

78   established (Gallet et al. 2007; Hounslow and Muttoni, 2010; Maron et al. 2019; Zhang et al.

79   2020; Ogg et al. 2020). However, the magnetic polarity pattern in some parts of the Carnian

80   is less certain (Zhang et al. 2020; Hounslow et al. 2022a). In the Upper Triassic uncertainty

81   remains about an internationally agreed position for the base of the Rhaetian (Galbrun et al.

82   2020), although that for the base of the Norian is closer to formal acceptance (Hounslow et al.

83   2021b).

84   We determined a magnetostratigraphy from the Devon coastal outcrops, providing the

85   first detailed chronostratigraphy of the MMG. This provides a better understanding of the

86   synchronisation of the British Middle and Upper Triassic with respect to the much better

87   studied German Triassic. These data also allow re-assessment of the composite polarity

88   timescale through the Norian by using additional data from the Upper Chinle Formation (of

89   New Mexico and Arizona) and elsewhere. This suggests a revised GPTS that shows better

90   convergence of the astronomically scaled magnetostratigraphy from the Newark Supergroup

91   and biostratigraphically better-dated marine sections through the Norian-Rhaetian.

The Mercia Mudstone Group in the Wessex Basin

93   The sections exposed in the east Devon cliffs between the outfall of the River Sid [SY

94   129 873] at Sidmouth, and east of the outfall [SY 273 893] of the River Axe at Seaton

95   provide the type section of the Mercia Mudstone Group (Howard et al. 2008; Gallois, 2019

96   Fig. 1). A total of about 470 m of Mercia Mudstone Group sediments, predominantly red

97   mudstone (and some green) with a few thin beds of sandstone, are exposed in these sections.

98   There are minor gaps in the succession due to faulting with potentially larger gaps in the Axe

99   Valley Fault Zone (Fig. 1). Micro- and macro-fossils are largely absent in these mudstones.

100   The MMG was previously inferred to range in age from the early Ladinian to late Rhaetian

101   based on: a) Anisian-age vertebrates (Benton et al. 2002) and a magnetostratigraphy from the

102   underlying Otter Sandstone Fm (Hounslow and McIntosh 2003), b) Carnian miospores from

103   the predominantly green and grey mudstones in the Dunscombe Mudstone Fm (DMF) and

104   immediately adjacent units (Baranyi et al. 2019) and c) Rhaetian miospores from the Lyme

105   Regis Borehole (Warrington 1997) and miospores and magnetostratigraphy from the top-

106   most Branscombe Mudstone and Blue Anchor formations in the Bristol Channel Basin

107   (Hounslow et al. 2004).

108   The MMG comprises four formations and eight members (Gallois 2001) that crop out

109   in almost continuous coastal cliffs between Sidmouth and Seaton (Fig. 1; Table 1). Detailed

110   lithological logs and magnetostratigraphic sampling points for the sections between Sidmouth

111   and Haven Cliff are shown in the Supplementary Information (SI Figs. S1.1 to S1.7).

112   The red mudstones that make up most of the MMG are thought to have formed

113   largely in arid playa environments, with mud input likely via mud-pellets (Talbot et al. 1994;

114   McKie 2017), and/or loess accumulation (Jefferson et al. 2000; Mao et al. 2021). In more

115   marginal situations in the north-eastern part of the Bristol Channel Basin some horizons have

116   pedogenic features such as slickensides (Milroy et al. 2019). However, palaeosols are not

117   present in most of the MMG on the Devon coast but do occur within the Dunscombe

118   Mudstone Fm (DMF) and its immediately underlying unit. Sedimentological evaluation of

119   the DMF indicates it formed in a freshwater lacustrine environment with shallow channels

120   (Porter and Gallois 2008), with associated beds of halite/sulphate collapse breccias (Gallois

121   2003). Within this general pattern of sedimentation there are regional lithological variations

122   that are poorly understood in the absence of age-diagnostic indicators. However, overall

123   facies are like those of other Germanic-type facies in western Europe (Aigner and Bachman

124   1989; Reinhardt and Ricken 2000; Vollmer et al. 2008; McKie 2017). The Wessex Basin in

125   which these strata accumulated is a sag basin without bounding faults (Butler, 1998). Coeval

126   Upper Triassic basin-margin strata (carbonates and some coarse clastics) onlap basement,

127   with limited areal occurrence, in marginal units to the NW (Milroy & Wright, 2000; Milroy

128   et al. 2019). This basin therefore is tectonically quiescent in contrast to some other well

129   studied Upper Triassic basins, such as the Newark Rift Basin, where tectonism played a more

130   active role in sedimentation (Withjack et al. 2013).

Sampling and Methods

131

132   Samples were collected from 262 horizons, including four from the Pennington Point

133 Member (which overlap the sampling of Hounslow and Mcintosh (2003) from the Otter

134 Sandstone Fm). From these samples, 447 specimens were measured (Table 2), placed onto

135 sub-sections that represent natural continuously exposed segments of the MMG outcrop (see

136 SI section 1). Red mudstone horizons were preferred for sampling, if available, but non-red

137 lithologies were sampled in the DMF and Blue Anchor Formation (BAF). Sampling used

138 exclusively oriented hand-samples, prepared from suitable exposures, using hammers and

139 digging tools to expose a fresh block. Flat surfaces on these were oriented with a magnetic

140 compass and a specially designed 'foot-print' orientation staff (Hounslow et al. 2022b).

141 Samples were wrapped in the field for protection during transportation. Sampling was

142 segmented into subsections detailed in Table 2 and SI section S1.

143   In the laboratory, specimens were re-oriented and set in dental plaster, from which

144 cubic palaeomagnetic specimens were cut dry with a diamond saw (the mudstones tend to

145 fracture and crumble when exposed to saw coolant water).

146   Low field magnetic susceptibility (K) was measured using either an AGICO

147 Kappabridge or Bartington MS2 meter. Measurements of Natural Remanent Magnetisation

148 (NRM) were made using a 3-axis CCL GM400 cryogenic magnetometer (noise floor ~ 0.002

149 mA/m with holder correction). Red mudstone specimens were subjected to stepwise thermal

150 demagnetisation, using a Magnetic Measurements Ltd, MMTD1 thermal demagnetiser, in

151 100-50°C steps up to 720°C, with most steps above 400°C. Magnetic susceptibility

152 measurements were performed after each heating step, to monitor mineralogical changes

153 caused by the heating, which were mostly minor (see SI). Some non-red samples from the

154 DMF and BAF (41 specimens in total) were measured by a combination of thermal

155 demagnetisation up to around 300-400 °C followed by reverse-tumbling AF demagnetisation

156 (on a Molspin demagnetiser). This procedure was used to limit thermal alteration which

157 obscured the characteristic remanent magnetisation (ChRM) in these lithologies. The

158 specimen demagnetisation results were analysed using principal component analysis in the

159 LINEFIND software (Kent et al. 1983), to extract the Triassic ChRM from the specimen data

160 (See Hounslow and McIntosh 2003; Hounslow et al. 2008a; 2021a for analysis details). Great

161 circle type behaviour was also shown by many specimens during demagnetisation, and

162 behavioural classes S (for linear -fits) and T (great circle behaviour) were assigned to

163 specimens (see demagnetisation behaviour panel in Figs 2 to 7). These were further sub-

164   divided into three qualitative classes (S1, S2, S3 and T1, T2, T3; with class 1 the top quality)

165   based on the directional scatter and number of points in the fitted principal component data

166   (see Hounslow et al. 2008a; 2021a for classification details). Directional data for some of the

167   weakest intensity specimens was too erratic and these specimens were rejected (X-class).

168   Based on the approach to expected Triassic directions and the behaviour classes, the

169   specimen is assigned a polarity quality (R, R?, R??, ?, N??, N? or N), to indicate its reversed

170   or normal polarity status, with R? or N? indicating a polarity assignment of lower quality,

171   compared to R or N of top quality. '?' indicates the specimen could not be confidently

172   assigned a polarity (Figs. 2 to 8).

173   The specimen virtual geomagnetic pole (VGP_R) latitudes (Hounslow et al. 2022b),

174   were determined with respect to the reference mean VGP direction for either the Sidmouth

175   Mudstone (MS, MD samples), Dunscombe Mudstone (MW samples), Branscombe Mudstone

176   (ML, SH, MB, SE samples) or Haven Cliff (HC samples) data. Values of VGP_R latitude near

177   +90º indicate a normal polarity specimen and values near -90º indicate reverse polarity (Figs.

178   2 to 8). Directional statistics (see SI Table S3.1) were determined with PMagtool v.5

179   (Hounslow 2006).

180   The magnetic mineralogy of the red mudstones of the Sidmouth Mudstone Fm was

181   described by Creer (1957, 1961), and additional data are given in SI section 2, confirming

182   haematite dominates the natural remanent magnetisations (NRM) in most of the MMG.

183   Statistical t of the magnetic polarity correlations was determined by firstly

184   characterising the polarity pattern in terms of five metrics for each magnetozone, t_0, $\log_e(t_{-1}/t_0)$,

185   polarity bias, Shermans ω_2 statistic and geometric mean. Where t_0 is the thickness (or

186   duration) of the magnetozone, and t_{+1}, t_{-1} are the corresponding values for the underlying and

187   overlying magnetozones. The later three metrics use t_{+1}, t_0 and t_{-1}. $\log_e(t_{-1}/t_0)$ is used in

188   quantitative polarity correlation since it is less dependent on sedimentation rate changes

189   (Man, 2008; Lallier et al. 2013). The polarity bias, ω_2 and mean thickness metrics

190   characterise more about the local polarity structure than using t_0 or $\log_e(t_{-1}/t_0)$ individually

191   (Olsen et al. 2014) and have been used in quantitative multivariate polarity correlation

192   (Hounslow et al. 2022b). Using these metrics for each magnetozone the polarity correlation

193   models were evaluated for statistical similarity using the similarity of matrices index (SMI)

194   and Procrustes similarity index (PSI) using methods in Indahl et al. (2018), The probability of

195   association of the corresponding polarity patterns uses the RV-based statistic P_{RV} (Josse et al.

196   2007). Lastly the divergent characteristics of each magnetozone in the correlation models was

197   characterised by the Euclidean distance (d_i) using the above five metrics above, in which

198   more problematic intervals of correlation are highlighted with larger d_i. Care was taken to

199   approximately normalise the five metrics to similar means and standard deviations. This

200   involved using $\log_e(t_{-1}/t_0)*0.5$ and $2*\omega_2$ and most-often scaling magnetozones to duration (in

201   Myr). This allows comparison of the median of d_i (d_{median}), as an additional approximate

202   measure of overall polarity pattern divergence. Statistical comparisons used R.

203   We also provide a preliminary assessment of the sequence stratigraphy of the MMG,

204   which is used with an assessment of the wider regional implications of this study. Details of

205   sequence boundaries selected are indicated in SI Table S1.2. These use the playa-lacustrine

206   environmental models proposed by Aigner and Bachman (1989), Reinhardt and Ricken

207   (2000) and Vollmer et al. (2008).

Results

209   NRM intensity is broadly related to colour, with red-mudstones having intensity 1-7

210   mA/m, and others 0.03- 1.5 mA/m (left panels in Figs. 2 to 8). The multi-coloured lithologies

211   from the DMF have a less simple relationship to NRM intensity (Figs. 4a; see SI section 2).

212   Demagnetisation behaviour shows two components: a low laboratory unblocking temperature

213   (LT) component and a dual polarity ChRM at the highest unblocking temperature. The LT

214   component typically ranges from NRM or 100 °C to around 350°C, but in some specimens

215   can extend to 500°C or more rarely to 600°C (See SI section 3). The LT component typically

216   dominates the magnetisation, which rapidly demagnetises in intensity towards 400 °C (SI

217   section 2). The Fisher mean of the LT component (in geographic coordinates) is 349°, +53°

218   (α_{95}=5.9°, k=3.3, n=245) and may be partly a Brunhes-age component, but with many

219   specimens displaying partial overlap with the Triassic components (see SI section 3 for

220   details and demagnetisation plots). However, the mean inclination is shallower than expected

221   for the Brunhes (~67°), indicating the LT component could be partly acquired during the

222   Early Cretaceous, when the MMG were eroded and onlapped (Fig. 1).

223   The ChRM in red mudstones is shown predominantly by linear fits to the high

224   temperature steps (on average from 480 °C to 680-700 °C or the origin; see SI section 3), but

225   with some more unusual specimens having ChRM that unblocks from 150-400 °C. In the non-

226   red lithologies from the DMF, ChRM ranges are 300-400°C to 40 - 80mT or the origin.

227   Linear fits comprise data from 62% of specimens (S-class data points in Figs. 2 to 8, 255

228   specimens). The ChRM identified by great circle trends toward the expected direction (T-

229   type behaviour; Figs. 2 to 8), comprised 32% of specimen data (133 specimens). The

230   remaining 6% of specimens failed to yield useful directional data either due to complete LT

231   and ChRM component overlap or absence of a ChRM (indicated as X-class). A total of 88%

232   of specimens were assigned polarity using the two better categories of polarity quality (i.e. N,

233   R, N?, R?).

234   Mean directions were determined for each section using either the S-class directions

235   (Fig. 9) or additionally using the great circle data from the T-class specimens (SI Table S3.1).

236   Directions mostly pass the reversal test with class Rb or Rc, and the derived palaeopoles are

237   like other Triassic poles from stable Europe (see SI section 4).

238   ***Magnetostratigraphy***

239   Magnetozones are assigned to 12 major magnetozone couplets labelled SS1 to SS12

240   (Sidmouth to Seaton composite section), with SS12 in the Seaton Cliff section. The basal

241   reverse magnetozone in the MMG is labelled BS8r, continuing the labelling used by

242   Hounslow and McIntosh (2003) for the Budleigh Salterton to Sidmouth sections in the

243   Sherwood Sandstone Group (Fig. 2). The Haven Cliff section uses a separate magnetozone

244   code (HC1n to HC3r; Fig. 8) because its relationship with the SS-magnetozones is less

245   secure.

246   The lower ~140 m of the MMG between the River Sid outfall to Hook Ebb (Figs. 2,3)

247   is composed of 11 magnetozones, with the thickest magnetozone (SS1n) in the whole of the

248   group at 36 m, in the Salcombe Hill Mudstone Mb (Fig. 2). The polarity in the top of the

249   Otter Sandstone Formation (Pennington Point Mb) east of Sidmouth is consistent with that

250   previously measured in the same interval west of Sidmouth by Hounslow and McIntosh

251   (2003), and their correlated data are also shown on Fig. 2. Some larger sampling gaps are

252   present in the Hook Ebb Mudstone Mb (Fig. 3), and three of the magnetozones are defined by

253   single samples (2 specimens each; SS2r.1n; SS3n.1r) in the Salcombe Mouth to Hook Ebb

254   section (Fig. 3). Polarity data of Creer (1959) from the lower part of this section identifies the

255   base of a normal polarity magnetozone some 17 m above a green sandstone level, which is

256   presumably near the top of the Otter Sandstone, and normal polarity below the sandstone

257   level, with an intervening reverse magnetozone some 17-22 m thick. These polarity changes

258   are like our data, but reverse magnetozone (BS8r) is some double the thickness of Creer's.

259   Lithological logs were not given by Creer (1959), so either; a) these differences relate to a

260   thickness error, or b) the upper part of BS8r in Creer's data was too strongly overprinted by

261 the LT overprint, that AF demagnetisation at 120 mT (and 3 years storage in zero field) failed

262 to remove it.

263   The SS1n-SS3r polarity boundary coincides with the basal sandstone bed in the base

264 of the Salcombe Mouth Mb, indicating there could be a hiatus at this level. Similarly, the

265 SS2r-SS3n polarity boundary coincides with a halite breccia bed so it could be there is a

266 hiatus between samples MD1 and MD4 across this ~1 m breccia interval.

267   The 45 m of section at Strangman's Cove preserves 18 magnetozones, with three

268 additional tentative reverse magnetozones in the upper part of the Little Weston Mudstone

269 Mb (SS3n.2r, SS3n.3r, SS3n.4r; Fig. 4). This part of the Little Weston Mudstone Mb was one

270 of the least well exposed parts of the MMG (at the time of sampling), and the sparser

271 sampling probably inadequately represents the polarity changes. The high sampling density in

272 the lower and mid parts of the DMF indicates frequent reversals, or a relatively condensed

273 interval in the MMG. The Lincombe Sandstone Mb (a lenticular siltstone/sandstone body if

274 evaluated using adjacent outcrops) is exclusively reverse polarity (SS4r; Fig. 4). The change

275 in polarity across the base of the Lincombe Sandstone Mb could indicate a hiatus at its base.

276 Likewise, the halite breccias in the section likely indicate a hiatus in the section at these

277 levels (Fig. 4). An interval at -2.5 m with slickensides (Fig. 4) is a probable palaeosol. This

278 occurs in an interval of strata that is infrequently exposed in the upper part of the Little

279 Weston Mudstone Mb (172 -183 m in composite height; SI Fig. S1.3).

280   The stratigraphically higher but partially overlapping 45 m section at Littlecombe

281 Shoot west displays dominantly reverse polarity with a single-sample normal magnetozone in

282 the lowest Littlecombe Mudstone Mb (SS8r.1n; Fig. 4). Samples from the upper sandstone

283 are of reverse polarity (magnetozone SS9n.1r; Fig. 5) embedded in a thicker normal polarity

284 magnetozone SS9n, which extends into the base of the section at Littlecombe Shoot east (Fig.

285 5a). The magnetostratigraphy in the Littlecombe Shoot Mb may be more complex than the

286 sampling indicates, because seven of the submagnetozones in this member are based on only

287 single samples (but 2 specimens from each, e.g., basal part of SS9r; Fig. 5).

288   The section between Red Rock and Branscombe Mouth starts in reverse magnetozone

289 SS9r (Fig. 6), like the upper-most sampled part at Littlecombe Shoot east, but passes up into

290 normal polarity (SS10n, SS11n), which is dominant in the mid and upper parts of this section

291 (Fig. 6). Two submagnetozones are defined by a single sample, one at the base of the Seaton

292 Mudstone Mb (SS9r.3n), and one at ~48 m above the base of the Seaton Mudstone Mb

293 (SS11n.1r; Fig. 6).

294   The Seaton Cliff section is dominated by normal magnetozone SS12n, but with three
295   submagnetozones defined by single samples (SS12n.1r, SS12r.1r, SS12r.1n; Fig. 7).
296   The Haven Cliff section has well defined magnetozones, particularly those in the
297   uppermost Seaton Mudstone Mb and throughout the Haven Cliff Mudstone Mb where
298   sampling density is higher (i.e., HC2n; Fig. 8). The specimens from the BAF were
299   challenging to measure and analyse due to the weak NRM intensity (many <0.1 mA/m),
300   larger directional scatter, and dominance of great-circle type behaviour (Fig. 8). Four
301   magnetozones are defined by a single sample, with multiple specimens (HC1n.1r, HC1n.2n,
302   HC2n.1r and HC3r.1n), and three tentative submagnetozones (HC2n.2r, HC3n.1r, HC3r.2n;
303   half width bars in polarity column; Fig. 8) are defined by a single specimen. One sample has
304   specimens of opposite polarity and is assigned unknown polarity (grey bar at -11 m; Fig. 8).
305   Overall, the MMG magnetostratigraphy has a moderate number of magnetozones
306   defined by single samples (21 out of the total), which is a non-ideal situation, and could be
307   rectified with detailed sampling of sparse intervals.

Discussion and synthesis

Timing issues in red-bed magnetisations

310   The fine-grained haematite (the pigment) which colours many red-bed successions
311   generally has been generated over-long time intervals by oxic diagenesis. This pigment
312   component often largely carries the overprint magnetisations or it is sufficiently fine-grained
313   to acquire no persistent remanence. The specularite (haematite generally > 1μm in size) in red
314   beds is responsible for the stable magnetisations either produced during deposition, during
315   very early burial, or in some cases during longer-term diagenesis, like the pigment (see
316   reviews by Butler, 1992 and Swanson-Hysell et al. 2019). Some of the issues connected with
317   the 'red-bed controversy', which was most active in the late 1970-1980's, were also related to
318   the incomplete demagnetisation methods (i.e. blanket demagnetisation) often employed at the
319   time, which were unlikely to separate primary from secondary components and later
320   diagenetic-related magnetisations. These have now been superseded by more complete
321   demagnetisation approaches. It is clear from the work of Creer (1959, 1961) that the MMG
322   contains both pigment and specularite. Likely, the LT component in the MMG is largely
323   carried by the pigment, as evidenced by the often-rapid intensity decay during thermal
324   demagnetisation and unblocking of this component (see SI). Isolation of magnetisations in

325   randomly tilted intraformational intraclasts is the classic way to test for specularite

326   components acquired prior to deposition (Swanson-Hysell et al. 2019). Intraclasts are rare in

327   the MMG (and only of small size), so this method cannot be easily applied.

328   We infer that the ChRM in the MMG red-sediments is largely carried by detrital

329   haematite deposited during deposition (or close to that time). This is based on: 1) The ChRM

330   is carried by both haematite and magnetite in the DMF, which contains both normal and

331   reverse polarity intervals. The DMF red mudstones appear little different magnetically to

332   other parts of the MMG. 2) The ChRM directions are of dual polarity with palaeopoles much

333   like many other European Triassic sediments; 3) Magnetisations are simple in directional

334   behaviour, unlike those inferred to be acquired over long-term intervals which tend to be

335   more complex (Butler, 1992). 4) Magnetozones are straightforward to define, without many

336   single-sample polarity intervals, which could be a characteristic of patchy diagenetic

337   production of specularite.

338   However, it cannot be excluded that some of the specularite has been produced over

339   longer time intervals. This could be responsible for the great-circle type behaviour seen in

340   some specimens, so longer-term diagenetic-related magnetisations are not fully separated

341   from near-depositional components when demagnetised. The wide dispersion in the

342   declination of the poles to the great circles for the specimens with t-class ChRM's (SI Fig.

343   S3.2) is consistent with contamination from rather dispersed secondary components, perhaps

344   acquired over longer and variable time-intervals into the Brunhes (e.g., SI Fig. S3.1).

345   Possibly some of the 6% of specimens that retain no ChRM are dominated by magnetisations

346   from pigment or diagenetic specularite.

Age of the Sidmouth Mudstone Formation and international comparisons

348   Independent constraints on the age of the Sidmouth Mudstone Fm (SMF) are provided

349   firstly by vertebrates, largely from the Chiselbury and Pennington Point members (and some

350   older occurrences from the Otterton Ledge Member) of the underlying Otter Sandstone Fm

351   (Benton et al. 1994; Spencer and Storrs 2002; Gallois 2005; Coram et al., 2017). The key

352   taxon *Eocyclotosaurus* is largely known from the upper parts of the Otter Sandstone (Coram

353   et al., 2017). The age of these vertebrate assemblages has been inferred by comparison to

354   similar assemblages in better dated strata of the Röt Formation (in Germany) and the

355   Holbrook Member (Moenkopi Formation, USA) described by Lucas and Schoch (2002). The

356   Röt Formation in the CEB is early Anisian in age (Nawrocki and Szulc 2000; Szurlies 2007).

357   From the Moenkopi Formation (in Arizona), magnetostratigraphy from the Holbrook

358   Member suggests it has a late Anisian age range from magnetochrons MT4 to MT7, a

359   correlation also constrained by (CA-TIMS) U-Pb detrital zircon dates (Haque et al. 2021; Fig.

360   10).

361   In addition, vertebrate assemblages like those of the Otter Sandstone Fm occur in the

362   Bromsgrove Sandstone of the Midlands, which is inferred to be Anisian (Seyfullah et al.

363   2013), because the overlying MMG has Anisian age palynomorphs (Benton et al. 1994). In

364   contrast, fish remains from the Otter Sandstone Fm suggest a Ladinian age (Milner et al.

365   1990). The level of uncertainty in the widely inferred Anisian age for the Otter Sandstone

366   Fm, based on the vertebrates alone is unclear. Indeed, some have emphasized the inherent

367   uncertainties and flaws in the concept of land vertebrate faunachrons and their means of age

368   control (Rayfield et al. 2009; Irmis et al. 2010; Martz and Parker, 2017)

369   Secondly, age is inferred from miospores in the uppermost SMF, DMF and basal

370   Branscombe Mudstone (Baranyi et al. 2019). Two palynologically-productive samples some

371   38 m below the base of the DMF in the Wiscombe Park-1 borehole, were assigned to the

372   early Julian Substage (earliest Carnian) by Baranyi et al. (2019), a position some 6 m above

373   the base of the Little Weston Mudstone Mb (Gallois 2007).

374   The Little Weston Mudstone Mb palynology accords with the normal polarity

375   dominance of this member, which characterises the early part of the Julian (Fig. 10). The

376   underlying magnetostratigraphy from the remainder of the SMF seems a good match to the

377   GPTS in the mid and late Ladinian (Fig. 10). However, there are differences in the presence

378   of brief normal subchrons in MT11r, which are only seen from the Seceda core dataset

379   (Maron et al. 2019; Hounslow and Muttoni 2010). Other marine sections containing MT11r

380   such as Mayerling and Gammsstein-1 only have reverse polarity (Maron et al. 2019), like our

381   data from magnetozone BS8r (Fig. 10). These correlations suggest the base of the SMF

382   closely corresponds with the start of MT11r in the mid Ladinian.

383   The reverse polarity dominated mid and late Anisian (MT4r to MT8r) is a distinctive

384   polarity feature of the Middle Triassic (Fig. 10). This MT4r-MT8r interval is primarily

385   evidenced by well-dated magnetostratigraphies from the Mushcelkalk (Nawrocki and Szulc

386   2000), the upper Guandao section (Lehrmann et al. 2015; Li et al. 2018), and the Milne

387   Edwards Fjellet section on Svalbard (Hounslow et al. 2008b). The coeval upper part of this

388   interval (MT7 to MT8r) is also found in other sections from Italy, Greece, Austria, and

389   Svalbard (Hounslow et al. 2008b; Maron et al. 2019). The MT4r to MT8r chron interval is

390   most likely equivalent to the BS3r to BS6r magnetozones in the Otterton Ledge Mb of the

391   Otter Sandstone Fm (correlation option-1 in Fig. 10). This correlation option gives a fair

392   correspondence between the number and relative thickness of magnetozones in the BS6 to

393   BS8n interval and the two possible GPTS interpretations for this interval. Option-1 (our

394   preferred solution) places the base of the Ladinian close to the base of the Chiselbury Mb of

395   the Otter Sandstone (Fig. 10).

396   The differences between the GPTS of Hounslow and Muttoni (2010) and Maron et al.

397   (2019) in the MT4r-MT8r interval are due to use of the Guandao section data as the reference

398   section for the lower and mid parts of this interval by Maron et al. (2019). Whereas

399   Hounslow and Muttoni (2010) used more datasets for this interval. Because of the uncertainty

400   in this part of the GPTS, a second possibility is that the MT4r-MT8r interval represents BS3r-

401   BS5r, shown as correlation option-2 in Fig. 10. Option-2 results in more changes in

402   accumulation rate (if magnetochron thickness in the GPTS is a proxy for time) in the Otter

403   Sandstone Fm than option-1. Also, option-2 gives two additional reverse magnetozones in

404   BS7n.1n, BS7r which are not represented in MT11n. However, magnetochron MT11n is only

405   partially represented in the Belvedere and Aghia Triada sections, with both displaying a

406   tentative reverse submagnetozone near the base (Maron et al. 2019), so MT11n may contain

407   more reverse subchrons than shown in these reference sections. The loss of time at potential

408   hiatuses in the Otter Sandstone at the base of the Chiselbury and Pennington members

409   appears to be small, although perhaps all three correlation options suggest part of MT8r

410   (SC2r in GPTS-A) may be missing, based on the thinner reverse polarity of BS6r.

411   The statistical evaluation of these correlations shows that correlations to GPT-A

412   (Option-1) gives the better and larger SMI (0.53), but the correlations to GPTS-B give the

413   larger PSI value (Table 3). As a comparison the GPTS-A to GPTS-B statistics show a higher

414   level of similarity, as would be expected, because both are constructed from mostly similar

415   datasets. The median Euclidean distance is smaller (0.48) for the correlation to GPTS-B,

416   suggesting this has some advantage over the correlations with GTS-A. All three correlation

417   options pass the RV-test of similarity at >99% probability (P_{RV} <0.01; Table 3). The more

418   problematic magnetozones (i.e., with larger d_i) for comparison are Anisian magnetochrons

419   MT4r and MT5n using GPTS-B, and BS3r.2r, BS5r, BS6n.1n for GPTS-A (flagged in Fig.

420   10). All correlation options indicate magnetochrons MT12n and MT11 have larger d_i

421   indicating these are more problematic comparisons.

14

Comparison to the Triassic of the Central European Basin (CEB)

In the CEB the Longobardian to early Carnian interval are assigned to the Grabfeld Fm (Bachmann and Kozur 2004; Nitsch et al. 2005; Hagdorn and Nitsch 2009), largely based on miospore correlations (Kürschner and Herngreen 2010). Regionally the Grabfeld Fm is divided into three units (lower, middle, and upper) with boundaries locally expressed as disconformities (Nitsch, et al. 2005), but in the Morsleben 52a core as correlative conformities. Sulphate bearing units largely occur in the Lower and Middle Grabfeld Fm, like those seen in the Hook Ebb Mudstone and Little Weston Mudstone members (Fig. 11). A magnetostratigraphy through the Grabfeld Fm in core Morsleben 52a and associated northern CEB cores (Fig. 11), allowed construction of a composite for this formation (Zhang et al. 2020), which has a connected cycle-stratigraphy (Barnasch 2010). The magnetostratigraphy from the Lower and Middle Grabfeld Fm and upper part of the underlying Urfurt Fm shows a fair correspondence to the upper part of the SMF (Fig. 11). This suggests the maximum regressive surface in the Salcombe Mouth Mb may relate to the upper-most regressive interval in the Erfurt Fm, below the flooding surface expressed by the transgressive, marine Grenzdolomit horizon. This correlation is emphasised by the sulphate bearing interval between SS2r to basal SS3n and the dominance of coeval evaporites, typical (Nitsch et al. 2005) of the Middle Grabfeld Fm (Fig. 11). Possible hiatuses may be at the base of the Salcombe Mouth Mb and the base of magnetozone SS2n where there is coincidence of polarity boundaries and beds with distinctly differing lithology to underlying units. In the CEB the Urfurt Fm, unlike the overlying Grabfeld Fm contains sandstone beds, a simple comparison which also applies to the Salcombe Mouth Mb and the overlying Hook Ebb Mudstone pair of units. Therefore, as an approximation the interval from the base of the Pennington Point Mb to the base of magnetozone SS2n is coeval with the mid and upper parts of the Urfurt Fm (Figs. 10, 11), which has a strongly diachronous boundary with the underlying Muschelkalk (Franz. et al 2013)

Correlation of the MMG polarity data to the GPTS is ambiguous around the base of the Carnian. Firstly, miospores place the base of the Carnian below the productive samples in the Little Weston Mudstone Mb (Baranyi et al. 2019), and near the base of the Upper Grabfeld Fm in the CEB (Bachmann and Kozur 2004; Kürschner and Herngreen 2010). Secondly, uncertainty about the GPTS construction in the early Carnian (Julian-1 interval) also leads to duplicate options for correlations of magnetozones SS3n and MK2n (Fig. 11). The most likely correlation for the bases of SS3n and MK2n is with the base of UT1n in both

455   GPTS-A and GPTS-B (Fig. 11). If the single specimen of conodont *Paragondolella*

456   *polygnathiformis* (conodont proxy for the base of the Carnian; Rigo et al. 2018) found in the

457   Carnian GSSP at Stuores is representative of its first appearance, then UT1n and UT2n may

458   be duplicates in GPTS-B, and instead magnetochron MA5 (in GPTS-A) may be

459   representative of this interval (Fig. 11). This would suggest SS2r and MK1r are the likely

460   equivalents of MT13r (and MA4r), a magnetochron which so far only has a

461   thickness/duration estimate from the Mayerling section (Gallet et al. 1998).

462   The upper part of magnetozone SS3n in the Little Weston Mudstone Mb has

463   insufficiently detailed sampling to properly define a polarity stratigraphy. However, by

464   comparison to the upper part of the Grabfeld Fm, it is clear this interval is either condensed,

465   or contains a hiatus. The most likely candidates for either of these scenarios are the palaeosol

466   at 179 m or its underlying halite collapse breccia (Fig. 11). If a hiatus, this may be coeval

467   with a disconformity often inferred at the base of the Upper Grabfeld Fm (Bachmann and

468   Kozur 2004; Hagdorn and Nitsch 2009; Kozur and Weems 2010).

469   ***Age of the Dunscombe Mudstone Formation (DMF) and international comparisons***

470   Independent evidence of the age of the DMF are firstly provided using miospores

471   from the Strangman's Cove section, in which Baranyi et al. (2019) placed the Julian-Tuvalian

472   boundary around the upper boundary of the DMF. Their miospore data from the body of the

473   DMF suggest that most of this formation is late Julian (or Julian) in age. Warrington (1971)

474   similar concluded that palynomorph assemblages from the DMF were Carnian in age, and

475   Fisher (in Jeans, 1978) recognised older and younger Carnian palynomorph assemblages with

476   the boundary between them placed within the Lincombe Sandstone Mb. Warrington (1997)

477   also inferred a Carnian-age in two samples from the Lyme Regis Borehole, which probably

478   come from the DMF (Gallois 2006). However, the precision with which the Julian and

479   Tuvalian substages can be identified with miospores in the MMG is uncertain, because as

480   noted by Baranyi et al. (2019), miospore occurrences are often diachronous between the

481   Triassic Germanic and Tethyan realms, and independent age control is poor for miospores

482   from the inferred Tuvalian and Norian of the Germanic realm (Kürschner and Herngreen

483   2010). Characterising the Carnian-Norian transition using miospore assemblages more

484   generally is also problematic (Cirilli 2010; Lucas et al. 2012; Hounslow et al. 2021b).

485   Secondly, a single specimen of the spinicaudatan, *Laxitextella multireticulata* (Reible)

486   was found in the Lincombe Sandstone Mb from fallen blocks at Weston Mouth (Kozur in

487 Gallois 2019). This species also occurs in the Middle and Upper Grabfeld Fm of the CEB

488 (Geyer & Kelber, 2018), and from the Upper Meride Limestone of the southern Alps (Kozur

489 & Weems, 2010). The Upper Meride limestone is early Longobardian in age (Stocker et al.

490 2012), currently providing the best age calibration of *L. multireticulata* . However, the range

491 of *L. multireticulata* is unknown in detail, and more 'advanced forms' have been described,

492 similar to the younger *L. laxitexta*, which is known to range into the Norian (Geyer & Kelber,

493 2018). Until more is known about the age range of *L. multireticulata* a single specimen from

494 the DMF cannot be confidently used to infer precise ages.

495 Thirdly, age can be inferred using negative carbon-isotope excursions (CIE) found in

496 the DMF both in the Strangman's Cove section and the Wiscombe Park boreholes (Miller et

497 al. 2017; Baranyi et al. 2019; marked on Hook Ebb-Strangman's Cove section in Fig. 12 as

498 DIE#). These provide additional means of correlation to marine sections with better age

499 control. The Carnian possesses several CIE in the Julian which are in part well calibrated to

500 biostratigraphy (Mueller et al. 2016; Dal Corso et al. 2018; Lu et al. 2021; Mazaheri-Johari et

501 al. 2021; Li et al. 2022). These are marked on the Ogg et al. (2020), GPTS-A in Fig. 12 (as J1

502 to J4); although these are less well-calibrated to magnetostratigraphy. CIE also occur in the

503 Tuvalian and basal Lacian interval (Jin et al. 2019; Hounslow et al. 2022a; marked on the

504 GPTS-B column (T1 to L1) in Fig. 12) and are better calibrated to magnetostratigraphy.

505 The magnetostratigraphy from the late Tuvalian and Julian is generally well

506 characterised by section-based studies from Turkey, Italy, Austria, Slovakia and China

507 (Hounslow and Muttoni 2010; Maron et al. 2019; Figs 11, 12). However, the

508 magnetostratigraphy of the early Tuvalian (Tuvalian-1; Fig. 12) is less certain, and one option

509 is to project the poorly-dated Stockton Formation dataset (Newark Supergroup, E-numbered

510 magnetozones) into the mid Carnian (Figs. 12, 14). This option is used in GPTS-A (Fig. 12)

511 and by Zhang et al. (2020), based on magnetostratigraphy from the northern CEB cores.

512 However, Hounslow et al. (2022a) have proposed a rather different polarity scale for the

513 Tuvalian (GPTS-B; Fig. 12), based partly on polarity datasets from Svalbard and constrained

514 by CIE correlations in the Tuvalian.

515 In terms of geomagnetic polarity, the most distinctive feature of the Lacian Substage

516 is the dominance of reverse polarity (Newark magnetozones E8r-E12r; chrons UT13r-UT16r;

517 Fig. 14). This clearly associates the dominant reverse polarity in the top of the DMF and

518 lower Littlecombe Shoot Mb (SS7 to SS8r) to the Lacian (Figs. 12, 15). This correlation

519 places the base of the Norian within SS6r.1n or SS7n in the upper part of the DMF (Fig. 12).

520   This part likely has missing intervals at the halite collapse breccias in the section (breccias in

521   SS6-SS7 magnetozones). The preferred correlations shown in Fig. 12 (magnetozones SS5r

522   and SS6n to GPTS-B) are based on the correlation of the DMF isotope excursions DIE4,

523   DIE5 to CIE (T5+T6) and T4 respectively (Fig. 12). Magnetozones SS5n and SS6n may

524   additionally correspond with magnetozones MK5n.1n and MK5n.2n in the Weser Fm from

525   the northern CEB cores (upper red correlation lines in Fig.12).

526   The Little Weston Mudstone Mb and basal DMF are normal-polarity dominated and

527   hence the Julian-1 magnetochron interval UT1n- UT2n in GPTS-A, may correlate with the

528   pattern of polarity changes inadequately represented by the sampling in this part of the MMG

529   (Fig. 12). Overlying chron UT2n (blue labels on GPTS-A) is a reverse polarity dominated

530   interval (MK3r-MK4r at Morsleben; SS3r-SS4r in the DMF), which is probably equivalent to

531   the UT6r - UT9r interval in the GPTS-B (based on data from Svalbard and the Pignola-2

532   section; Maron et al. 2017; Hounslow et al. 2022a). In the DMF the isotope excursion DIE-3

533   likely correlates to the J3+J4 excursions (Mazaheri-Johari et al. 2021) of Julian-2 age (black

534   correlation line in Fig. 12). Based on the association of normal polarity around DIE-1, and the

535   dominantly reverse polarity in UT3r-UT4r, it seems less likely that DIE-2 is the equivalent of

536   excursion J2 known from the earliest Julian-2 (Fig. 12). A better alternative is that a missing

537   interval may be present at the halite collapse breccia in SS3r, and DIE-2 and DIE-1 are

538   probably older CIEs within Julian-1 (e.g., as in Mueller et al. 2016). This suggests the reverse

539   polarity of the Lincombe Sandstone Mb is coeval with that of the Stuttgart Fm in the

540   Morsleben cores, and both are early Tuvalian in age. Since the polarity changes across the

541   base of the Lincombe Sandstone Mb, this level could be a minor hiatus/missing interval (Fig.

542   13) because this sandstone has a channel-like (but not clearly down-cutting) geometry (Porter

543   and Gallois 2008).

544   A magnetostratigraphy from the Polish 'Schilfsandstein' (Nawrocki et al. 2015,

545   Wójcik et al. 2017) has indicated three normal polarity submagnetozones, in a dominantly

546   reverse polarity interval like the style of polarity changes in the Stuttgart Fm of the

547   Morsleben cores; although in Poland fragmentary recovery of polarity from over and

548   underlying strata precludes any detailed correlation. Refinement of the association of carbon

549   isotope excursions with respect to the magnetostratigraphy in the late Julian would assist with

550   international correlation at a finer scale.

551   The statistical assessment of these correlations shows that SMI is largest for the DMF

552   to Morsleben correlations, with the largest PSI for the DMF to GPTS-B correlations (Table

553   3). This later correlation also has the smallest median d_i (at 0.77), and the larger probability of

554   association (more than 99% chance of association). This suggests statistically the correlation

555   to GTPS-B is the better, with the most problematic intervals for comparison being SS4r,

556   SS6n and SS6r.1r (Fig. 12). For comparison, the GPTS-A to GPTS-B correlations have

557   smaller SMI and PSI indices, indicating poorer relationships. This is probably because these

558   are constructed from entirely different polarity datasets through the Tuvalian.

559   *Comparison to the Stuttgart and Weser formations of the CEB*

560   At a simple-level, the sandstone and calcareous 'group' divisions of Jeans (1978) for

561   the DMF (Fig. 13) are like the halite-sandstone-halite bearing 'sandwich' of the Stuttgart Fm

562   and its adjacent formations in the CEB (Bachmann et al. 2010; Hagdorn and Nitsch 2009).

563   The presence of dolostone beds in both successions also enhances the degree of similarity to

564   the DMF, with flooding surfaces in the CEB usually represented by dolostone beds. Using the

565   magnetostratigraphic correlations and the events and cycles of Barnsach (2010) from the

566   Morsleben 52a core, and Franz et al. (2014) from more widely in the CEB, some of these

567   flooding surfaces may have coeval expression in the Devon successions; particularly those of

568   the Neubrandenburg, Beaumont and Lehrberg beds (Figs. 12, 13). However, the small cycles

569   of Barnsach (2010) do not have a clear synchronous expression in the DMF.

570   The set of halite-dissolution breccias in the Upper Weser Fm from the Moresleben

571   52a core, and those near beds K and J in the DMF may be indicative of coeval flooding

572   events around the base of the contemporary SS7r and MK5r.1r magnetozones (Fig. 13).

573   Indeed, three widely distributed halite units are known in the CEB in the Weser Fm

574   (Bachmann et al. 2010), which may be coeval with the three collapse breccias seen in the

575   upper part of the DMF between 26- 30 m (Fig. 13). If these relationships are correct, the

576   boundary between the Weser and Arnstadt formations (the D4 or early Kimmerian-I

577   unconformity; Feist-Burkhardt et al. 2008) may be coeval with the sequence boundary at bed

578   N in the base of the Littlecombe Shoot Mudstone Mb (Fig. 13).

579   Despite episodic eustatic marine influence on the Middle Keuper in the CEB (sourced

580   through a southern gateway; Bachmann et al. 2010; Franz et al. 2014), and the correlations

581   proposed in Fig. 13, there is no direct evidence for marine intervals in the Wessex Basin in

582   this interval. If there was, this would likely be a route from the SW through the SW

583   Approaches basins (McKie 2017). More detailed investigation of the dolostone intervals in

584   the DMF may shed light on this possibility.

585 ### *Rhaetian and upper Norian: Blue Anchor Formation (BAF), Seaton and Haven*
586 ### *Cliff Mudstone members*

587   In addition to the miospore data discussed above in the base of the Branscombe
588 Mudstone Fm, palynomorphs from the upper parts of the BAF suggest a Rhaetian age
589 (Warrington 1997, 2005). These Rhaetian assemblages are comparable to those from the St
590 Audrie's Bay section in North Somerset, where similar assemblages continue into the Penarth
591 Group (Hounslow et al. 2004; Bonis et al. 2010).

592   Alternative GPTS's have been proposed for the mid Norian to early Rhaetian. Firstly,
593 that of Kent et al. (2017) and Maron et al. (2019) utilise a reference scale largely from the
594 Newark Supergroup magnetostratigraphy (Fig. 15), with the chronostratigraphy imported
595 using a correlation to selected marine sections with magnetostratigraphy. Secondly, is the
596 GPTS-B (Fig. 14) a marine-section based composite of Hounslow and Muttoni (2010), which
597 is updated here with new data for the Sevatian to early Rhaetian (see SI Fig. S5.1).
598 Correlations between GPTS-B and some key non-marine sections for this interval are shown
599 in Fig. 14, with the addition of a composite for the upper Chinle Formation (its construction
600 is outlined in SI section 5.1). GTPS-B provides the better base to understand the likely
601 chronostratigraphy of the upper parts of the MMG (Fig. 15).

602   The magnetostratigraphy from the Haven Cliff section is closely comparable to that
603 from the St Audrie's Bay section (Fig. 15), even down to the reverse submagnetozones in the
604 coeval mid parts of HC2n and SA4n and the probably coeval reverse submagnetozones
605 SA3n.1r and HC1n.1r (Fig. 15). The relative thicknesses of coeval magnetozones varies
606 somewhat between these sections, but both are closely comparable to the
607 magnetostratigraphy from the upper Passaic Fm (E16n to E19 magnetozones) of the Newark
608 Supergroup (Fig. 15). These relationships are also consistent with an unanchored
609 astrochronology from the MMG at St Audrie's Bay and its synchronisation with the Newark
610 Supergroup cyclostratigraphy (Kemp & Coe, 2007). Newark magnetozones E15 to E19 are
611 widely associated with late Norian (Sevatian age strata) and their transition into the earliest
612 parts of the Rhaetian (Fig. 14; SI Figs. S5.1, S5.2; Maron et al. 2019). Based on these
613 magnetostratigraphic correlations, the two proposed choices for the base of the Rhaetian
614 (NRB1 and NRB2 in Figs. 14, 15), place the Rhaetian boundary either in the upper part of the
615 Haven Cliff Mudstone, or within the lowest part of the BAF (Fig. 15). This indicates that
616 magnetozone HC1n (in the Haven Cliff section) should equate to Newark magnetozone
617 E16n, St Audrie's Bay magnetozone SA3n and magnetochron UT22n.

618   The age of NRB1 based on the anchored astrochronology from Austrian sections

619   places it at ~208 Ma (Galbrun et al. 2020), consistent with both the placement of NRB1 (from

620   magnetostratigraphic correlations in Fig. 14) and the anchored astrochronological age (207.6

621   Ma; Kent et al. 2017) for the base of E18r in the Newark Supergroup (Fig. 14). Based on the

622   biostratigraphy from the Chinle Fm; the Redonda Mb (magnetozone CC8n-CC10n interval;

623   Fig. 14) is usually assigned a Rhaetian age (Zeigler and Geissmann 2011; Heckert and Lucas

624   2015). In addition, the similarity in Chinle Fm detrital zircon ages to the Newark-Hartford

625   APTS ages between CC5r-CC9n (E14r- E18n in Newark-Hartford APTS) indicates a close

626   correspondence between the polarity patterns in the Chinle Fm and Newark Supergroup (top

627   left Fig. 15), and the corresponding interval in GPTS-B. This locates NRB1 near the base of

628   magnetozone CC9r in the Chinle Fm composite, and consequently robustly demonstrates the

629   international consistency in the polarity patterns in this Sevatian to early Rhaetian interval,

630   from magnetochrons UT20r to UT24r (Fig. 14).

631   In the Wessex Basin the interval encompassing the Seaton Mudstone Mb to the base

632   of the BAF is regionally rather consistent in thickness (Gallois 2001; 2003), with the nearest

633   borehole to the coastal outcrops (at Marshwood) showing ~ 145 m (Gallois 2003) for this

634   interval. This is used as a thickness estimate for the Seaton Mudstone Mb in the coastal

635   outcrops. We consider that magnetozone SS12n is not the equivalent of either HC1n, SS11n

636   or SS10n, also in the Seaton Mudstone Mb, for the following reasons. Firstly, projecting the

637   top of the Seaton section (above the sampled interval), based on a test of the equivalence of

638   SS12n and HC1n, would indicate that the Haven Cliff Mudstone Mb should be close to the

639   top of the Seaton section; yet there is no evidence of the Haven Cliff Mudstone Mb in the

640   Seaton fault blocks. Secondly, the mudstones from the Seaton Mudstone Mb in the

641   Branscombe section, have cm-scale sandy laminae which are absent from the Seaton Cliff

642   section, suggesting these sections are not lithologically equivalent. Thirdly, SS11n is some 23

643   m thick compared to 14 m for SS12n and also have no consistent lithological matches using

644   the detailed logs (see the SI). Fourthly, SS10n (11 m thick) is a similar thickness to SS12n,

645   yet any lithological match, using the assumption of magnetozone equivalence is poor. Also,

646   this match would require the Red Rock Gypsum Mb to be shortly below the Seaton section, a

647   situation for which there is no evidence in the ~40 m of poorly exposed outcrop to the west in

648   the Axe valley fault blocks. The later three arguments suggest that magnetozone SS12n is not

649   equivalent to magnetozones SS11n or SS10n seen in the Branscombe Mouth section. Using

650   the above thickness estimate of the Seaton Mudstone Mb and the cumulative sampled

651   thicknesses of this member, indicates that ~26 m of this member remains unsampled from

652   this study.

653   Therefore, magnetozone SS12n is inferred to be magnetochron UT21n, as also seen in

654   the basal part of the St Audrie's Bay section (SA2n; Fig. 15 and E15n in the Newark APTS).

655   Additional support for this is that the pattern of polarity changes in the Seaton Cliff section is

656   like that in magnetozone CC6n in the Chinle Fm. Also, both the Pizzo Mondello and Kavur

657   Tepe sections have reverse sub-magnetozones in UT21n, like those detected within CC6n and

658   SS12n, similarities strengthening this proposed correlation.

659   *The Branscombe Mudstone Formation and the middle Norian (Alaunian)*

660   The interval from magnetozones SS9n to SS11n contains three major normal polarity

661   intervals (SS9n, SS10n, SS11n), like both the marine-based GPTS-B, and the interval CC4n

662   to CC5n in the upper Chinle Fm composite (Fig. 15). For this reason, and the constraints

663   from overlying and underlying polarity patterns, we correlate the interval SS9n - SS11n with

664   UT18n - UT20n (Fig. 16). However, this interval is unlike the Newark Supergroup APTS,

665   which has only two thick normal magnetozones over this interval. This suggests that the

666   Newark Supergroup magnetozone interval E14n-E14r may be incomplete (marked in Fig.

667   15). Other than the marine-based sections over this interval, there are also coeval non-marine

668   sections from the Fleming Fjord Group and the Los Colorados Fm (Fig. 14). The middle

669   Norian interval has also been evaluated in cores and sections from the Holy Cross Mountains

670   in Poland (Wojcik et al. 2017) through the Arnstadt Formation, which displays a pattern of

671   polarity reversals similar in overall style to the UT18n to UT21n, although the fragmentary

672   recovery of polarity precludes a detailed comparison.

673   The magnetostratigraphy from the Fleming Fjord Group does not extend to older

674   strata to confirm the polarity pattern UT18n-UT20n, but matches well with GTPS-B (Fig.

675   14), using the preferred correlation of Kent and Clemmenson (2021) and the coeval parts of

676   the Newark APTS. Some 60 m below the base of the Colorados Fm is a precise ID-TIMS

677   zircon date (i.e., 221.8 ±0.3 Ma), which when compared to the Chinle Fm composite (with its

678   detrital zircon dates), suggests the magnetostratigraphic match shown as Option-2 in Fig. 14.

679   The correlation shown as Option-1 was that preferred by Kent et al. (2014) based on the less

680   precise Ar/Ar date (225.9 ±3.7 Ma), which also gives a satisfactory polarity match between

681   the upper part of the Colorados Fm and magnetochrons UT18n to UT20n (Fig. 14), but

682   unsatisfactory match using the more precise ID-TIMS date.

683   The proposed missing interval in the Newark APTS (marked in Figs. 14, 15)

684 corresponds with an abrupt upwards decrease in accumulation rate near the boundary of

685 magnetozones E14n-E14r (from ~24 to 14 cm/ka), based on the astrochronology using depth

686 rank and colour (Meyers 2019; Wang et al. 2022). This suggests an abrupt and major shift in

687 sedimentary regimes at the proposed position of the missing interval.

688   These strands of evidence, along with the new data from the MMG, although not

689 conclusive by themselves, collectively support the Newark APTS to GPTS-B correlation

690 shown in Figs. 14, 15. Significantly this solution may solve the long-running debate (Gallet et

691 al. 2003; Muttoni et al. 2004; Hounslow and Muttoni 2010; Galbrun et al. 2020; Ogg et al.

692 2020) about how the Newark APTS in the mid Norian relates to the marine-based GPTS.

693 This conundrum is fundamentally linked to ambiguity in how to relate the biostratigraphy of

694 the Newark Supergroup to international stages (Tanner and Lucas 2015; Galbrun et al. 2020).

695 With the solution proposed here, the chronostratigraphic and biostratigraphic divisions of the

696 Norian are now satisfactorily aligned with the astrochronology from the Newark Supergroup

697 (Fig. 14). This interpretation indicates the Branscombe Mudstone Fm contains the full

698 complement of magnetochrons known from the early Norian to the early Rhaetian (Fig. 15).

699   The statistical evaluation of these correlations shows that the GPTS-B to Chinle

700 composite show the strongest association with the largest SMI, PSI and smallest median d_i

701 (Table 3). The Newark Supergroup APTS to Chinle composite shows a similar level of

702 association as between the GPTS-B and the MMG, with all three of these having a

703 probability of association > 99% (P_{RV} <0.01; Table 3). Magnetozones SS9n.2n, SS9r.3r,

704 HC2n.2n and HC2r, have the larger d_i indicating more divergence of these zones. These

705 statistics support the overall correlation relationships proposed above. They also suggest that

706 in spite of the very different tectonic and sedimentologic settings of these three terrestrial

707 successions, they all share a common record of polarity changes which is not impacted to a

708 major extent by hiatus. This does not mean that these successions are complete, as inferred at

709 the hiatuses in the MMG, it may just indicate that at the time-scale of polarity changes, the

710 sediment record is sufficiently complete to approximate the relative length-scales of most

711 major magnetochrons.

Controls on accumulation rates in the Mid-Late Triassic in Britain

713   With the proposed correlation to the polarity scales, we estimate accumulation rates in

714 the Otter Sandstone Fm and Mercia Mudstone Group. Attachment of polarity boundaries to

715   chronometric time used the Bayesian age model of Hounslow et al. (2018) for the Middle

716   Triassic to early Carnian (polarity chrons up to UT5n). The late Carnian to Rhaetian interval

717   used the Newark Supergroup astrochronology of Kent et al. (2017) and Wang et al. (2022),

718   which give only slightly different ages for the magnetochrons. That using the Bayesian age

719   model and Kent et al. (2017) ages is referred to as age model-1 and that using the Bayesian

720   age model and Wang et al. (2022) ages is model-2 (Fig. 16). As an alternative to the late

721   Ladinian-Carnian part of these models we also use the chronometric scale proposed by Zhang

722   et al. (2020). Alternatively, Miller et al. (2017) proposed a 1.09 Myr duration (based on an

723   astrochronology from the Wiscombe Park borehole) for the interval from the base of the

724   DMF to near the correlated base of magnetozone SS6r. This same interval gives a duration of

725   7.0 Myr and 8.1 Myr using age model-1 and the Zhang et al. (2020) age model respectively.

726   Likely the ca 8 m cycles identified by Miller et al. (2017) are closer to 2.4 Myr eccentricity

727   cycles.

728   Using these three age models, instantaneous accumulation rates between polarity

729   boundary ages were estimated (data points in Fig. 16). The accumulation rates are not

730   significantly impacted by the inferred missing interval in the Newark Supergroup APTS,

731   because rates are based on chron durations. Since the age estimates of polarity boundaries in

732   the MMG are likely biased by sampling resolution and fidelity of polarity recovery, and by

733   uncertainties in the chronometric estimation of magnetochrons in the age models, we have

734   averaged the accumulation rates (using a 3-point geometric mean) for the model-1 and

735   Carnian age models (Fig. 16). The alternate Carnian age model does not significantly modify

736   the accumulation rates. These accumulation rates also include the potential missing time at

737   the likely hiatus levels identified.

738   These data indicate thye Devon coastal succession overall has a baseline

739   accumulation rate of 30-50 m/Myr throughout this interval, which presumably relates to

740   typical subsidence and accommodation space availability in this part of the Wessex Basin.

741   There are several deviations from the baseline rates (Fig. 16).

742   In the upper part of the Otterton Ledge Mb there is a reduction of accumulation rate to

743   ~10-20 m/Myr, which corresponds with the upper part of the 2nd fluvial cycle of Newell

744   (2018a) in this member. This reduction in accumulation rate corresponds with the Anisian-

745   Ladinian boundary interval. In the northern part of the CEB the Illyrian-Fassanian boundary

746   also corresponds with the initial regression of the Lower Keuper (Erfurt Fm) over the marine

747   limestones of the Upper Muschelkalk. In the southern CEB, with a stronger marine influence,

748   this diachronous regression was completed in the late Fassanian (Franz et al. 2013). The

749   facies shift expressed by Muschelkalk-Keuper transition is the major environmental change

750   of the Middle and Upper Triassic Germanic facies in Europe. Our dating shows that the Otter

751   Sandstone-MMG transition (Chiselbury to Sid Mudstone members) is coeval with this

752   diachronous environmental shift. However, the Wessex Basin was not hydrologically

753   connected to the CEB (McKie 2014) in this interval. More importantly in the Wessex Basin

754   this transition shows a transgressive relationship. The transgressive character is shown most

755   clearly above the sequence boundary (Gallois 2005; Newell 2018a) at the base of the

756   Pennington Point Mb, which is an erosive transgressive surface with an overlying

757   transgressive system tract (TST) extending into the Salcombe Hill Mudstone Mb (Fig. 16).

758   The nature and boundaries of the Pennington Point Mb indicate it genetically belongs to the

759   MMG successions (Gallois 2003). Although the CEB and the Wessex Basin have opposite

760   sequence stratigraphic tracts in this age interval, they both show a flood of silt-and clay-grade

761   siliclastics overwhelming carbonate and fluvial sand-prone systems respectively. In the CEB

762   the source of sand was predominantly from Scandinavia in the Keuper (Paul et al. 2008), but

763   from Cadomian basement rocks of the Armorican Massif throughout the Otter Sandstone Fm

764   (Morton et al. 2013). The likely common factor linking the incoming Erfurt Fm and MMG

765   successions was an increasing aridification and greater supply of loessic silt and clay during

766   the transition into the Ladinian. Loessic silt may have had a bigger impact on the dry-playas

767   (McKie 2017), of the Sidmouth Mudstone Fm, than in the CEB, where wet-playa facies tend

768   to dominate in coeval mudstones (Aigner and Bachmann, 1989; McKie 2017).

769   The DMF shows the largest reduction in accumulation rates, which began in the upper

770   part of the Little Weston Mudstone Mb and shows recovery through the lower part of the

771   Littlecombe Shoot Mudstone Mb (Fig. 16). This dramatic reduction in accumulation rates is

772   likely associated with Carnian environmental changes that are best understood in the mid-

773   Carnian (Dal Corso et al. 2020). Probable causes of this large reduction in accumulation rate

774   are:

775   A. **Fine-sediment bypass**: the sink for detrital fines was largely directed to basin

776   depocenters with sand- grade material remaining at basin margins and within channel

777   systems that are directed to basin depocenters (Porter & Gallois 2008). Certainly,

778   during the Carnian much greater thicknesses of halite accumulated in depocenters in

779   the Wessex Basin (Gallois 2003), probably coeval with the halite-breccia intervals

780   above and below the sand-bearing interval in the DMF. The basin-flank halite

781 deposits were likely re-worked during ephemeral periods of high groundwater and re-

782 charged to depocenters (McKie 2017), as inferred in the CEB by Franz et al. (2014).

783 A similar style of Carnian-age, by-pass basin-filling is seen in the CEB, giving

784 distinctive depocenter sags from filling of accommodation space, particularly during

785 the interval of the Grabfeld Fm (Bachmann et al. 2010). Alternatively, this geometry

786 is commonly inferred as a pulse of renewed extensional tectonics (Bachman et al.

787 2010; McKie 2017), rather than flank condensation with sediment by-pass and

788 accommodation spacing filling. Rejuvenated extensional subsidence does not concur

789 with the observed reduction in basin flank accumulation rates.

790 B. **Shut down in fine sediment supply** from hinterlands and desert margins: This comes

791 about by lack of supply, perhaps caused by enhanced vegetation trapping in hinterland

792 soils or lakes, so that loessic sources areas ceased to supply the same volume of fines,

793 yet the limited supply of fluvial-derived sand+fines continued. At the present-day,

794 desert dusts in low latitudes are principally supplied from desert margins, with the

795 largest single sources being from deflation of lake basins (Bristow et al. 2009),

796 providing seasonally phased supplies of dust (Middleton 2017; Li et al. 2020).

797 The conundrum of the mid Carnian in western European Germanic-style basins is the

798 sedimentological indication of sandy, wetter lacustrine and fluvial systems in the mid Carnian

799 (Porter and Gallois 2008; Kozur and Bachmann 2010; Franz et al. 2019; Ruffell et al. 2015),

800 yet palynological data suggest similar dry-land vegetation (xerophytes) throughout the

801 Carnian crisis (Baranyi et al. 2019; Franz et al. 2019). One way to balance this apparent

802 dichotomy is a flashier riverine input, so that ephemeral/seasonal storms deliver the sand-

803 grade material, yet ground water and soil moisture is not maintained throughout the growing

804 season, so hygrophytic flora was not able to fully develop, a situation which has been

805 proposed for the Carnian of the Wessex Basin (Baryani et al. 2019). A greater contribution

806 from xerophytic regionally-derived pollen rain, may also have limited the ability to detect

807 local hygrophytic vegetation that developed during these brief wetter intervals. This

808 imbalance may have been enhanced by spread of hinterland xerophytes, into previously

809 hyper-arid areas, due to seasonally more humid, but annually essentially dry desert margins.

810 This may be linked to point B above. Franz et al. (2014) have proposed an alternative

811 scenario for the Stuttgart Fm in the CEB invoking marine transgressions as the forcing factor

812 for local development of hygrophytes, which is not applicable in the Wessex Basin due to a

813 lack of evidence for marine influence.

814   The dry playa facies of the Branscombe Mudstone Fm do not reach maximum

815   accumulation rates until the mid Norian, at around the position of the Red Rock Gypsum Mb,

816   which likely represents an interval of wet-playa facies (i.e., facies divisions of McKie 2017),

817   probably marking a maximum flooding surface. A second maximum flooding surface in the

818   late Alaunian corresponds with a distinctive high gamma pick seen consistently on log

819   profiles in the Wessex Basin (Gallois 2003; Newell 2018b). This likely relates to an interval

820   with cm-thick black mudstones which are exposed on the low tide beach below the Seaton

821   section (so likely in magnetozone UT20r; Fig. 15). This 'high gamma event' heralds a decline

822   into lower accumulation rates in the upper Seaton Mudstone Mb, and the development of

823   wet-playa facies in the Haven Cliff Mudstone Mb and BAF. Since the units above the Red

824   Rock Gypsum Mb are consistent in thickness across the Wessex Basin (Gallois 2003), the

825   likely reason for the accumulation rate decrease may be increasing humidity into the Sevatian

826   and early Rhaetian, impacting sediment supply, like outlined in B) above.

827 **Conclusions**

828   1. A magnetostratigraphy is recovered from most of the 474 m of the Mercia Mudstone

829   Group from coastal outcrops in the type-section of the group. Some outcropping intervals

830   need refining, because the sampling density is inadequate to robustly define some thin

831   magnetozones.

832   2. Characteristic magnetisations are largely carried by haematite, but with some rare levels

833   in the Dunscombe Mudstone Fm where magnetisations are carried by magnetite.

834   3. The magnetostratigraphy can be correlated with better dated marine and non-marine

835   sections elsewhere, and thus establishes the first accurate chronostratigraphy for the

836   MMG. The interval studied ranges from the early Ladinian (mid Fassanian Substage) to

837   the early part of the Rhaetian. Other geochronological tools applied to the MMG, such as

838   cyclostratigraphy, may assist in improving and adapting the proposed age assignments.

839   4. Using our data and a collective assessment of magnetostratigraphies from other Norian

840   sections, allows us to proposal a solution to the long-standing debate about the polarity

841   pattern through the mid Norian.

842   5. The interval of the Hook Ebb Mudstone to Little Weston Mudstone members is closely

843   comparable in facies and age to the Grabfeld Fm in the CEB.

844   6. A comparison of our magnetostratigraphy to that from the Middle Keuper Group of the

845   CEB indicates a close similarity to the Dunscombe Mudstone Fm, including the

846   equivalence of sandstone-bearing intervals of the Lincombe Sandstone Mb and the

847   Stuttgart Fm of the CEB. The coeval nature of some flooding surfaces and the timing of

848   evaporites between the Dunscombe Mudstone Fm and the Weser Fm of the CEB

849   indicates synchroneity of some climatic events between these two basins. Additional

850   work on the more sparsely-sampled upper part of the Little Weston Mudstone Mb would

851   improve the chronology of this apparent Julian age interval.

852   7. Using the derived age models of the Devon succession, accumulation rates are

853   dramatically lower from the mid Carnian, but show recovery in the early Norian. These

854   changes reflect sediment by-pass on the flanks of the Wessex Basin and a major

855   slowdown in fine sediment delivery. This was likely due to limited aeolian supply of dust

856   from shrinkage of the hyper-arid source areas, caused by seasonal climatic humidification

857   from the mid Carnian to earliest Norian.

858   8. The data detailed here enables environments and habitats in the Middle-Late Triassic in

859   Britain to be better related to other widely geographically spaced localities and it should

860   improve details of palaeogeological maps, bringing the British Triassic succession into

861   much better time-alignment with the Germanic Triassic.

Figure Captions

Fig. 1. Geological sketch sections of the Mercia Mudstone Group outcrop in the cliffs between Sidmouth in the west and Bindon Cliffs (east of Seaton). All sections projected onto a west-east line. Drift deposits and minor landslides omitted for clarity. Inset shows location in UK.

Fig. 2. Summary of the magnetostratigraphic data for the Sidmouth to Salcombe Mouth section. A) simplified sedimentary log (see SI Fig. S1.1 for detailed log) and magnetic susceptibility (MS) and initial natural remanent magnetisation (NRM) intensity (each point represents a demagnetised specimen). B) Demagnetisation behaviour classification of specimen data. C) Specimen polarity classification. D) Virtual geomagnetic pole latitude (VGP_R) with respect to the formation mean pole, with S-class data with filled symbol and T-class data with unfilled symbol; E) interpreted polarity and section lithostratigraphy. MZ=labels of magnetozone couplets (BS8r is a continuation of that used by Hounslow and McIntosh (2003) for the Budleigh Salterton to Sidmouth Section); SS=Sidmouth to Seaton sections.

Fig. 3. Summary magnetostratigraphic data for the Salcombe Mouth to Hook Ebb section. See Fig. 2 for column details. See SI Fig. S1.2 for detailed log.

Fig. 4. Summary magnetostratigraphic data for the Strangman's Cove section. See Fig. 2 for column details. The position of the organic matter carbon isotope excursions of Miller et al. (2017) and Baranyi et al. (2019) are shown as (C). See SI Fig. S1.3 for detailed log.

Fig. 5. Summary magnetostratigraphic data for the Littlecombe Shoot sections. Upper panels are the western section, and lower panels the eastern section. See Fig. 2 for column details. See SI Fig. S1.4 for detailed log. DMF=Dunscombe Mudstone Fm.

Fig. 6. Summary magnetostratigraphic data for the Red Rock to Branscombe Mouth section. See Fig. 2 for column details. See SI Figs S1.4 and S1.5 for detailed logs.

Fig. 7. Summary magnetostratigraphic data for the Seaton Cliff section. See Fig. 2 for column details. See SI Fig.S1.6 for detailed log.

Fig. 8. Summary magnetostratigraphic data for the Haven Cliff section. See Fig. 2 for column details. See SI Fig. S1.7 for detailed log.

Fig. 9. Specimen S-class ChRM directions for the sections. A) Sidmouth Mudstone Fm and Pennington Point Member from the Sid outfall to Hook Ebb sections. B) The Strangman's Cove section, largely in the Dunscombe Mudstone Formation; C) The

1326   Littlecombe Shoot sections in the Littlecombe Shoot Mudstone Member. D) The Red

1327   Rock Gypsum and Seaton Mudstone Members in the Branscombe Mouth and Seaton

1328   Cliffs sections; E) Haven Cliff section. See SI Table S3.1 for mean directions and

1329   other directional tests.

1330 Fig. 10. Magnetic polarity correlations for the interval from the middle part of the Otter

1331   Sandstone Fm and lower part of the Sidmouth Mudstone Fm. GPTS-A from Maron et

1332   al. (2019), Ogg et al. (2020) and GPTS-B from Hounslow and Muttoni (2010). Otter

1333   Sandstone data from Hounslow and McIntosh (2003), with lithostratigraphy of

1334   Newell (2018a) and Gallois (2001). PPM= Pennington Point Member. See text for

1335   description of option-1 and option-2 correlations. Details of the statistical

1336   comparisons are in the SI.

1337 Fig. 11. Correlation of the upper part of the Sidmouth Mudstone Fm to the Erfurt to Grabfeld

1338   formations of the Central European Basin (Morsleben polarity from Zhang et al.

1339   2020). Likely correlation to the GPTS composites of Hounslow and Muttoni (2010)

1340   and Maron et al. (2019) are indicated. The differences between the two GTPS are

1341   related to the differences in correlation between the marine Stoures and Mayerling

1342   sections. GPTS-B uses that proposed by Broglio Loriga et al. (1999), GPTS-A use the

1343   first occurrence of the conodont *Paragondolella polygnathiformis* (Mietto et al. 2012;

1344   a single specimen at Stuores). The base of Julian-2 (J2) in GPTS-A is based on

1345   conodonts in Zhang et al. (2017), and in GPTS-B conodonts of Gallet et al. (1998).

1346 Fig. 12. Comparison of the magnetostratigraphy of the Carnian-age interval of the MMG with

1347   the GPTS-A of Ogg et al. (2020) and GPTS-B of Hounslow et al. (2022a). The

1348   correlation of the Morsleben core data to the GPTS-A is that of Zhang et al. (2020).

1349   Position of negative carbon isotope excursions (C) shown are based on Fig. 5 for the

1350   MMG excursions (labelled DIE# on MMG column), Hounslow et al. (2022a) for the

1351   Tuvalian-Lacian excursions (CIE, T1 to T6 & L1), and Dal Corso et al. (2018) and

1352   Mueller et al. (2016) for the Julian excursions (J1- J4 on GPTS-A).

1353 Fig. 13. Comparison of the Dunscombe Mudstone Fm (DMF) to the cycles and

1354   magnetostratigraphy of the Morsleben cores. Bed labels on DMF from Gallois and

1355   Porter (2006). Cycles in Morsleben 52a from Barnasch (2010), and lithostratigraphy

1356   from Franz et al. (2014). Red arrows are possible sequence stratigraphic correlations.

1357   Seq.= sequence stratigraphy outlined in SI Table S1.2.

1358 Fig. 14. Summary data for composite magnetostratigraphy through the Norian and early

1359   Rhaetian, modified from Hounslow and Muttoni (2010) (see SI section 5 for source

1360   details). See SI Fig. S5.3, S5.4 and SI section 5.1 for details of the upper Chinle

1361   Formation composite and detrital zircon ages. Newark Supergroup

1362   magnetostratigraphy from Kent et al. (2017), with astronomically anchored ages from

1363   their table 3. Red arrowed bar is the estimated stratigraphic uncertainty range in

1364   placing the radiometric date of Furin et al. (2006) onto the magnetostratigraphy. *E.*

1365   *quadrata* (*E. abneptis* A) and *E. slovakensis* (*E. n. sp*. D) conodont biozones are from

1366   Krystyn et al. (2009), others from Rigo et al. (2018). Fleming Fjord and La Sal

1367   section data from Kent and Clemmenson (2021) and Kent et al. (2014) respectively.

1368   Radioisotopic dates below La Sal section described in Irmis et al. (2022).

1369 Fig. 15. Correlation of the magnetostratigraphy of the Norian-Rhaetian part of the MMG to

1370   the GPTS-B from Fig. 14. The likely missing interval in the Newark Supergroup in

1371   the middle of the E14 magnetozone is explained in the text. NRB1 and NRB2 are the

1372   positions proposed for the base of the Rhaetian of Krystyn et al. (2007) and Rigo et al.

1373   (2016) respectively. Magnetostratigraphic composite for upper Chinle Fm from SI

1374   Fig. S5.4. St Audrie's Bay data from Hounslow et al. (2004).

1375 Fig. 16. The accumulation rates for the Otter Sandstone Fm and the Mercia Mudstone Group,

1376   using three age models. Symbols represent 'instantaneous' accumulation rates using

1377   the magnetochron durations, and the lines are geometric means of three adjacent

1378   instantaneous accumulation rates. Abbreviations: -M= Member, -MM= Mudstone

1379   Member, PP= Pennington Point, SH=Salcombe Hill; SM=Salcombe Mouth;

1380   HE=Hook Ebb; LW=Little Weston, LS=Littlecombe Shoot; RRG=Red Rock

1381   Gypsum; S= Seaton, HC=Haven Cliff; BAF=Blue Anchor.

Formation	Member [thickness, metres]	Type locality
Blue Anchor Fm (BAF)	[c. 30 incomplete] on Devon coast	Blue Anchor, Somerset
Branscombe Mudstone Fm (BMF)	Haven Cliff Mudstone Mb [20]	Haven Cliff
	Seaton Mudstone Mb [c.115 incomplete]	Branscombe Mouth to Seaton
	Red Rock Gypsum Mb [9.5]	Red Rock
	Littlecombe Shoot Mudstone Mb [78.6 incomplete]	Littlecombe Shoot
Dunscombe Mudstone Fm (DMF)	[35.7 incomplete[1]]	Strangman's Cove
Sidmouth Mudstone Fm (SMF)	Little Weston Mudstone Mb [34.6]	Hook Ebb
	Hook Ebb Mudstone Mb [63.4]	Salcombe Mouth to Hook Ebb
	Salcombe Mouth Siltstone Mb [11.0]	Salcombe Mouth
	Salcombe Hill Mudstone Mb [60.5]	Salcombe Hill to Salcombe Mouth
	Sid Mudstone Mb [15.5]	Sid outfall to Salcombe Hill
Otter Sandstone Fm (Sherwood Sandstone Group)	Pennington Point Mb [22]	Pennington Point (Sid outfall)

Table 1. Lithostratigraphic subdivision of the Mercia Mudstone Group exposed on the Devon coast (after Gallois, 2001, 2019).

Fm=Formation; Mb= Member. [1]Later sections have shown up to 41 m for the DMF.

Table 2. Summary of magnetostratigraphic sampling from the Mercia Mudstone Group, Sidmouth to Haven Cliff. Thicknesses are those shown on the SI FigsS1.1 to S1.7. Localities shown on Fig. 1, and details in SI Table S3.1. N=Number of specimens ;Ns= Number of sampled horizons.

Table 3. Statistics for the comparison of magnetic polarity correlation models in this work. The reference and comparison are the polarity patterns correlated, as shown in the figure number, using the magnetozone/chron ranges indicated. SMI, PSI= similarity of matrices index and Procrustes similarity index determined as in Indahl et al. (2018), with ranges 0-1.0 (no to perfect similarity). P_{RV}= the RV-based statistic testing the probability of association between the two sets (<0.05=strong association) as in Josse et al. (2007). d_{median}= median Euclidean distance of the number of magnetozones/chrons in the comparison (Nc), larger d_{median} correspond to larger average divergence. Absent/extra= magnetozones absent from the reference GPTS set used/ additional magnetozones in the comparison set not shown in the reference set. See SI for data details.
