14 Abstract

15 In this study, an electrochemical and aptamer-based aptasensor was developed for the sensitive
16 detection of patulin, a mycotoxin commonly found in fruits and fruit-based products. The aptasensor
17 used an innovative structural switching signal-off platform for detecting patulin. The aptamer
18 immobilization on screen-printed carbon electrodes was achieved through Au electrodeposition and
19 thiol group (-SH) route. Response surface methodology was used to determine the optimal incubation
20 times for the aptamer, blocking agent, and target molecule, which were found to be 180 minutes, 40
21 minutes, and 89 minutes, respectively. The response of the aptamer to different concentrations of
22 patulin was measured using square wave voltammetry by exploiting the structural switching
23 mechanism. The sensor response was determined by quantifying differences in the aptasensor's
24 background current. The aptasensor exhibited a linear working range of 1-25 µM and a low detection
25 limit of 3.56 ng/mL for patulin. The aptasensor's relative standard deviation and accuracy were
26 determined to be 0.067 and 94.4%, respectively. A non-specific interaction was observed at low
27 concentrations of two other mycotoxins, ochratoxin A and zearalenone. The interference from
28 ochratoxin A in the measurements was below 10%. In real sample tests using apple juice, interference,
29 particularly at low concentrations, had changed the recovery of patulin negatively with a significant
30 effect on the structural switching behaviour. Nevertheless, at a concentration of 25 ng/mL, the
31 interference effect was eliminated, and the recovery standard deviation improved to 6.6%. The
32 aptasensor's stability was evaluated over 10 days, and it demonstrated good performance, retaining
33 13.12% of its initial response. These findings demonstrate the potential of the developed

34 electrochemical aptasensor for the sensitive detection of patulin in fruit-based products, with prospects
35 for application in food safety and quality control.

37

38

39 **1. Introduction**

40 Food safety is a critical subject that necessitates the implementation of consistent precautions and
41 robust monitoring throughout the entire food supply chain, from agricultural production to consumption.
42 This comprehensive process encompasses various stages, including the sourcing of raw materials,
43 food processing, the attainment of the final product, and its subsequent storage [1]. To enhance the
44 effectiveness of analytical techniques employed for identifying hazardous constituents in food samples,
45 it is of utmost importance to advance the development of novel receptors that exhibit heightened
46 affinity towards specific targets. These receptors play a pivotal role in enabling the rapid, sensitive, and
47 reliable detection of potentially harmful components [2].

48 Mycotoxins are secondary metabolites with a relatively low molecular weight (around 700 Da) that
49 have the potential to contaminate a wide range of agricultural commodities. This contamination can
50 occur at different stages, including during cultivation in the field and storage [3]. These toxic
51 compounds can enter the human food chain either through direct consumption or indirectly through the
52 consumption of animal-derived products from animals that have ingested feed contaminated with
53 mycotoxins [4]. More than 100 fungal species have been identified as producers of approximately 400
54 potentially toxic mycotoxins [5, 6]. These mycotoxins, including trichothecenes, ochratoxins, aflatoxins,
55 zearalenone, fumonisins, patulin, and citrinin, are considered highly toxic and pose significant risks to
56 agriculture, livestock, and public health [7].

57 Patulin (PAT) is a specific mycotoxin known to contribute to the toxicity of food, with a notable
58 presence in apples [8-11]. It is classified as a secondary metabolite produced by various fungal
59 species, such as *Penicillium expansum* (*P. leucopus*), *P. patulum* (*P. urticae*, *P. griseofulvum*), *P.*
60 *crustosum*, and *A. clavatus* [12, 13]. PAT, characterized by its low molecular weight, water solubility,
61 and thermal stability [14], represents a significant global food safety concern. It is frequently
62 encountered in fruits and vegetables owing to their high moisture and sugar content. The severity of
63 acute PAT poisoning's detrimental effects on various organs [15] escalates in correlation with the
64 ingested quantity [16]. Consequently, the consumption level of contaminated food assumes crucial
65 importance, particularly among infants and children [17]. To mitigate the risks associated with acute
66 and chronic PAT exposure, regulatory bodies such as the World Health Organization (WHO), the Food
67 and Agriculture Organization (FAO), and the European Commission (EC) have established guidelines,

68 setting a maximum tolerable daily intake of 0.4 µg/kg body weight/day, restricting the maximum PAT
69 concentration in fruit juices to 50 µg/kg, and imposing a limit of 10 µg/kg for baby food products [16, 18]

70 Conventional methods employed for PAT detection, such as high-performance liquid
71 chromatography (HPLC) and enzyme-linked immunosorbent assays (ELISAs [19]), offer high reliability
72 [20-22]. However, they suffer from limitations including time-consuming sample preparation, the need
73 for skilled personnel, and the requirement for expensive equipment. These constraints hinder their
74 practical application in field settings [23, 24] Given the acute symptoms observed in both humans and
75 animals [25], as well as the genotoxic, mutagenic [26], immunotoxic, neurotoxic [27], and teratogenic
76 [28] properties associated with PAT, rapid and facile detection methods are of paramount importance
77 for ensuring human health and food safety. To overcome these challenges and enable rapid on-site
78 analysis, the development of innovative sensing platforms becomes imperative. Promising avenues in
79 this regard include aptamer-based, enzyme-based, and antibody-based biosensors [9, 13, 18].
80 Aptamers are single-stranded oligonucleotides composed of DNA or RNA that are derived from a
81 random or combinatorial library [29, 30]. These aptamers possess the ability to specifically interact with
82 target molecules, resembling the interactions observed between antibodies and antigens [31]. The
83 process of aptamer generation involves a technique called systematic evolution of ligands by
84 exponential enrichment (SELEX), which entails iterative rounds of exponential enrichment to select
85 aptamers with high affinity for a specific target [32]. The simplicity and effectiveness of aptamer
86 generation via SELEX have positioned them as promising alternatives to antibodies, overcoming their
87 fragility and challenging production, leading to their designation as "synthetic antibodies" [33-35].
88 Notably, DNA-based aptamers exhibit enhanced stability compared to antibodies. Their remarkable
89 stability, exceptional selectivity, and facile surface modification capabilities render aptamers optimal
90 molecular recognition elements for various biosensor applications [36]. Moreover, aptamers offer
91 several advantages such as the detection of small molecules, facile detachment from immobilized
92 surfaces, reusability, and cost-effectiveness [37]. Despite the significant prevalence of PAT as a
93 contaminant and its consequential economic and public health risks, there is a noteworthy scarcity of
94 research studies employing aptamer-based approaches for the specific detection of this mycotoxin
95 [16].

96 In recent years, aptamer-based sensors have emerged as highly promising tools for the detection of
97 diverse analytes. Various transduction techniques, including electrochemical, optical, and
98 spectroscopic methods, have been employed in aptasensors for mycotoxin detection. Khan *et al.*
99 reported the development of a fluorescence-based aptasensor for the detection of PAT in apple wine
100 samples, yielding toxin recoveries ranging from 96% to 98% [23]. Ma *et al.* described a fluorometric
101 PAT sensor based on a combination of magnetic nanoparticles, reduced graphene oxide (rGO), and
102 DNase I, achieving a remarkable detection limit of 0.28 ng/mL [38]. A study focusing on a
103 homogeneous fluorescent aptasensor, with broad applicability for the detection of various food
104 contaminants, demonstrated excellent performance of the PAT aptasensor in apple juice within a linear

105 dynamic range of 0.05-1 ng/mL [39]. For the detection of PAT in apple juice, a sophisticated
106 fluorescent aptasensor was developed using sulfur quantum dots encapsulated in MOF-5-NH₂ and a
107 self-cycling catalytic hairpin assembly (scCHA) system. The results obtained exhibited a strong
108 correlation with HPLC analysis, confirming the aptasensor's exceptional specificity, anti-interference
109 capability, and reproducibility [40]. Gua *et al.* devised a surface-enhanced Raman scattering (SERS)
110 aptasensor by integrating a signal molecule and chitosan-modified magnetic nanoparticles with a gold-
111 silver core-shell structure. This aptasensor achieved remarkable recovery rates ranging from 96.3% to
112 108% in real apple juice samples [41].

113 The simplicity of operation, fast response time, and potential for portability are advantageous features
114 of electrochemical sensors [42]. Moreover, the strong affinity of aptamers for their target ligands has
115 gained significant attention in the field of biosensor development[43]. Exploiting the benefits of both
116 electrochemical sensors and aptamers, electrochemical platforms have been developed for the rapid
117 detection of PAT [44]. To improve the sensitivity of these electrochemical biosensors, various
118 nanomaterials have been employed to enhance signal amplification [45].

119 In a study conducted by Liu *et al.*, a panel of four distinct aptamers harboring diverse PAT
120 sequences was employed in electrochemical (EC) and photoelectrochemical (PEC) experiments to
121 elucidate their detection behaviors on electrode surfaces [42]. Through meticulous evaluation, the most
122 optimal aptamer was identified, demonstrating remarkable sensitivity in the detection of PAT within
123 apple puree samples, with detection limits of 30 fg/mL and 50 fg/mL [46]. In a subsequent investigation
124 by Xu *et al.* in 2019, an impedimetric methodology was adopted to develop a PAT sensor, wherein
125 graphene-like black phosphorus nanosheets (BP NSs) were strategically employed for the surface
126 modification of a glassy carbon electrode (GCE) [45]. Further enhancements were achieved by
127 functionalizing the BP-NS-GCE interface with gold nanoparticles and thiolated PAT aptamer, resulting
128 in a significantly reduced detection limit [47]. Another study implemented a dual-signal strategy for PAT
129 detection, leading to the development of a highly sensitive aptasensor. Notably, the synthesis of a gold
130 nanoparticle-black phosphorus heterostructure (AuNPs-BPNS) was executed to effectively amplify the
131 sensing performance. This aptasensor demonstrated a wide dynamic range spanning from 0.1 nM to
132 100.0 μM, along with an impressively low detection limit of 0.043 nM [12].

133 The response mechanism of an electrochemical sensor through structural aptamer switching
134 involves the direct transfer or tunnelling of the redox moiety signal, facilitated by a conformational
135 change induced upon the interaction of an aptamer modified with a redox center, such as methylene
136 blue (MB), with a small-molecule target like PAT [48]. This process is depicted in Figure 1, where an
137 initial signal is received (on) but subsequently diminishes (off) following the interaction. Structural
138 switching aptamer-based electrochemical sensors have been documented to demonstrate low
139 detection limits across diverse applications [49].

140 Incubation time and analyte concentration are among the parameters that have a profound effect on
141 biosensor performance [50]. Response surface methodology (RSM) is widely used for optimization of

142 foodborne pathogen detection in label-free electrochemical nucleic acid biosensors. RSM is a
143 combination of statistical and mathematical techniques used to design experiments, build models,
144 evaluate the influence of factors, and seek optimal conditions for desired responses. The traditional
145 practice of changing one variable at a time does not allow for evaluation of the combined effects of all
146 factors involved in the process. This creates a time-consuming methodology. [51]. It may lead to
147 misleading results due to overlapping interactions between input parameters. It should be noted that
148 sometimes these interactions may be more important than the effect of the independent variables. [52]
149 These limitations can be overcome by the use of RSM, which can identify and quantify various
150 interactions between different parameters.[51] In this study, it was aimed to obtain maximum efficiency
151 and minimum cost by using the RSM method.

152 This manuscript presents an electrochemical sensor based on aptamer switching for the selective
153 and sensitive detection of PAT. The sensor utilizes the principle of target-induced aptamer switching,
154 where the presence of PAT induces a conformational change in the aptamer, resulting in an
155 observable electrochemical signal. The developed sensor offers notable advantages, including
156 simplicity, rapid response time, affordability, and portability, rendering it a promising candidate for on-
157 site PAT detection in diverse food matrices. Additionally, the design, fabrication, and characterization
158 of the aptamer-based sensor are thoroughly elucidated, along with its performance in detecting PAT in
159 commercially available apple juice. Comparative analysis with conventional methods highlights the
160 sensor's analytical capabilities and underscores its potential as an alternative approach for PAT
161 detection.

162 **2. Materials and Methods**

163 **2.1. Instruments and Chemicals**

164 All electrochemical measurements in this study were conducted using an Ivium potentiostat (Ivium
165 Technologies, B.V., Netherlands) at a controlled temperature of $23\pm 2^\circ\text{C}$. Screen-printed electrodes
166 (SPEs, DRP-110) with a working electrode area of 0.126 cm^2 were purchased from a local distributor of
167 Dropsens. Chemicals employed in the experiments were procured from Sigma-Aldrich, unless
168 otherwise specified, and were of analytical grade. UPW with a resistivity of $18.2\text{ M}\Omega\cdot\text{cm}$ was used for
169 the preparation of aqueous solutions and rinsing steps. The MB-modified PAT aptamer probe (MB-
170 aptamer), specifically designed for the recognition of PAT selected from the literature [50] was obtained
171 from Ella Biotech (Germany). The nucleotide sequence and secondary structure at 23°C of the MB-
172 aptamer is given in Table S1 [50, 51]. The lyophilized aptamer was utilized without any additional
173 treatment and used as is.

174 **2.2. Instruments and Chemicals**

175 2.2.1. Au electrodeposition

176

177 SPEs were initially subjected to electrochemical cleaning using the linear sweep voltammetry (LSV)
178 technique. This involved applying a potential step of 1 mV in the range of 0 to -2 V with a scan rate of
179 20 mV/s in 0.1 M KCl. The purpose of this step was to eliminate impurities and ensure a clean surface
180 for the electrodes. After the electrochemical cleaning process, the SPEs were dried, and a solution
181 containing 1 mM chloroauric acid $[AuCl_4]^-$ in 0.1 M KCl was drop-cast onto the surface of the
182 electrodes. This step aimed to facilitate the deposition of a thin layer of gold (Au) on the electrode
183 surface. Subsequently, the coated electrodes, referred to as SPE/Au, were subjected to cyclic
184 voltammetry (CV) with 15 cycles in the range of 0 to -1.5 V at a scan rate of 50 mV/s [33]. This
185 electrochemical process induced the deposition of a visible layer of Au on the electrode surface,
186 thereby enhancing its sensitivity and performance. After the electrodeposition process, the SPE/Au
187 electrodes were washed with ultrapure water (UPW) to remove any residual impurities. They were then
188 dried ensuring they were free from moisture and ready for the subsequent step of aptamer
189 immobilization.

190

191

192 Fig. 1. The schematic representation of the principle of structural switching aptasensor platform for
193 PAT detection.

194 2.2.2. Aptamer immobilization

195 Aptamer immobilization was carried out using MB-modified aptamers with the sequence $SH-(CH_2)_6-$
196 Aptamer-AttoMB2. A 10 μ M solution of MB-aptamer in pH 7.4 phosphate-buffered saline (PBS)
197 containing 0.1 M PBS with 0.05% Tween-20 was prepared. A volume of 10 μ L of the 10 μ M MB-
198 aptamer solution (0.05% Tween-20 PBS) was applied to the surface of the SPE-Au electrode and
199 allowed to interact with the Au surface. Following incubation, the electrode was rinsed with the same
200 buffer and subsequently treated with 1 mM 6-mercapto-1-hexanol (MCH) to block the Au surface.
201 Surface active molecules were generally used to both reduce non-specific interactions [55] and

202 improve immobilization by balancing the interaction of the aptamer with the Au surface during the
203 immobilization stage of the aptamer [56]. The addition of Tween-20 in the buffer was intended to
204 enhance the interaction between the aptamer and the target analyte [52]. Finally, the electrodes were
205 washed with buffer and prepared for the detection of the target analyte (PAT) as SPE-Au/Apt.

206 To determine the presence of PAT, the electrodes incubated with different concentrations of PAT in
207 the buffer were subjected to square wave voltammetry (SWV). The SWV measurements were
208 performed within the potential range of (-0.8) to (-0.3) V, using a single scan, a signal magnitude of 10
209 mV, and a frequency of 25 Hz. The same procedure was repeated after incubating the electrodes with
210 PAT, and the resulting change in current between the two scenarios was recorded as the response of
211 the aptasensor. The overall schematic representation of the modification steps of the SPE/Au/Apt
212 electrode for the detection of PAT is given in Figure 2.

213
214 Fig. 2. The schematic representation of the production steps of the structural switching electrochemical
215 aptasensor for PAT detection [33].
216

217 2.2.3. Determination of the optimal aptamer, MCH, and PAT incubation duration times

218 To determine the optimal incubation times for aptamer, MCH, and PAT, the response surface method
219 (RSM), a central composite design method, was utilized in the optimization studies. RSM analysis,
220 based on the response of the PAT aptasensor, was performed to examine the relationship between the
221 aptamer, MCH, and PAT incubation times and the resulting current change. Statistical evaluations
222 were conducted, and the analysis results indicated that the quadratic method provided the most
223 suitable model for the experimental data. The experimental plan for the optimization studies, which
224 focused on aptamer modification, MCH modification, and PAT incubation time as key factors, along

225 with the determined optimum values based on statistical evaluations and the desirability function, can
226 be found in Table S2, Figure S1 [33].

227 **2.3. Determination of Analytical Performance**

228 The analytical performance of the SPE-Au/Apt electrodes was assessed using the SWV technique
229 with the electrodes initially tested in a PAT-free 0.1 M PBS (pH 7.4) solution to establish the baseline
230 response. Subsequently, the electrodes were incubated with various concentrations of PAT (1, 2, 5,
231 10, 25 ng/mL in 0.1 M PBS, pH 7.4) for 89 minutes. Following the incubation, the electrodes were
232 thoroughly washed with 0.1 M PBS (pH 7.4). The prepared SPE-Au/Apt/PAT electrodes were tested
233 using SWV in 0.1 M PBS (pH 7.4) solution, and the resulting current change between the two
234 conditions was recorded as the response of the aptasensor.

235 The calibration curve was constructed by plotting the maximum current change against the
236 corresponding PAT concentration. The calibration experiments were repeated three times using
237 different electrodes, and the standard deviation of the data points was determined. After calibrating the
238 aptasensor, the limit of detection (LOD) was calculated as 3 times the standard deviation (3σ) within a
239 95% confidence interval, where σ represents the largest standard deviation observed among the
240 repeated measurements.

241 **2.4. Interference, Real Sample, and Stability Tests**

242 Interference experiments were performed to assess the potential interference of two common
243 mycotoxins, OTA A (OTA-A) and ZEN, on the detection of PAT. During the optimized incubation
244 period, the current values resulting from the incubation of these interferents were examined. The SPE-
245 Au/Apt electrodes were initially tested without PAT, followed by incubation with concentrations of 5
246 ng/mL and 25 ng/mL of ZEN (PAT+ZEN) and OTA-A (PAT+ZEN+OTA), respectively. The experiments
247 were repeated three times (N=3) to ensure reliability and reproducibility.

248 For real sample testing, apple juice samples obtained from local markets were processed by mixing
249 them with an equal volume of ethyl acetate solution (99.5% purity, obtained from Merck) using a vortex
250 mixer, followed by centrifugation. The upper ethyl acetate phase (1 mL) was collected after phase
251 separation and diluted with 19 mL of PBS. Different concentrations of PAT (5 ng/mL, 10 ng/mL, and 25
252 ng/mL) were added to these prepared apple juice samples using the standard addition method. The
253 measured values were then compared with the calibration curve to assess the accuracy of PAT
254 detection in real samples.

255 Stability experiments were conducted to evaluate the electrode stability. The prepared SPE-Au/Apt
256 electrodes were stored at +4°C for 10 days after obtaining the baseline current value. After the storage
257 period, the electrodes were tested with PAT, and the percentage change in the current difference value

258 was calculated relative to the reference value. Furthermore, the electrodes were stored at +4°C for an
259 additional 10 days and tested again to assess the sensor response compared to the reference value.
260

261 **3. Results and Discussion**

262 **3.1. Au electrodeposition and aptamer immobilization**

263 The CV results depicting the Au electrodeposition on the SPEs are illustrated in Figure 3 (a). It was
264 observed that the Au coating reached a steady state with no significant changes in the voltammogram
265 after the initial three cycles. Subsequently, after 15 cycles, the surface was entirely coated resulting in
266 a visibly discernible layer of Au.

267 To optimize the performance of the electrode, the modification of the aptamer and MCH, as well as
268 the incubation durations for the target molecule (PAT), were conducted using RSM. The detailed RSM
269 experimental design can be found in Table S3, S4. The relationship between the durations of aptamer,
270 MCH, and PAT incubation and the resulting change in current were investigated based on the
271 response of the electrochemical PAT sensor. A higher current difference was preferred compared to
272 the bare electrode. Statistical evaluations indicated that the quadratic method provided the most
273 suitable model for the experimental data. Using the solution where the desirability function equalled 1,
274 the optimized values for the aptamer, blocking agent (MCH), and target molecule incubation durations
275 were determined as 180 minutes, 40 minutes, and 89 minutes, respectively. These optimized values
276 were subsequently employed for the production and analysis of Au-coated SPE electrodes in the
277 subsequent stages of the study.

278 The on-off sensor response, based on the molecular switching phenomenon, was evaluated in the
279 presence of PAT, and the results are presented in Figure 3 (b) for a PAT concentration of 25 ng/mL.
280 The electron transfer between the electrode and the MB probe allows for a current response, resulting
281 in the aptasensor being in the "on" state when PAT is absent. Conversely, incubation with PAT blocks
282 the current, leading to the aptasensor being in the "off" state. This "on-off" behavior suggests that the
283 electron transfer distance may depend on the number of PAT molecules bound to the aptamer,
284 enabling calibration for the quantitative measurement of PAT concentration in a given sample.
285

286

287 Fig. 3. (a) CVs for 1 mM [AuCl₄]-electrolysis at 0.1 M KCl at 50 mV for 15 cycles (b) Signal on-off signal
 288 response of the Aptasensor to PAT.

289

290 3.2. Determination of the Analytical Performance

291 The peak current density values obtained from electrodes incubated with PAT solutions of different
 292 concentrations (1, 2, 5, 10, 25 ng/mL in 0.1 M PBS, pH 7.4) were plotted to examine the changes in
 293 response. The calibration curve of the developed aptasensor is presented in Figure 4. The calibration
 294 curve was generated by conducting three replicates at each of the five PAT concentrations and
 295 calculating the average values. It was observed that the structural switching mechanism resulted in a
 296 proportional decrease in current intensity as the PAT concentration increased. This proportionality
 297 became more pronounced starting from a PAT concentration of 2 ng/mL, exhibiting a higher level of
 298 linearity (determination coefficient $R^2 = 0.993$). At lower PAT concentrations, it is expected that the
 299 switching events may not occur in sufficient numbers to produce a significant change in current
 300 intensity. However, within the range of 2 ng/mL to 25 ng/mL, the switching behavior displayed a highly
 301 linear relationship with a high coefficient of determination. Additionally, the repeatability analysis
 302 showed an average standard deviation of 0.055 μA and a maximum deviation of 0.067 μA . This
 303 deviation corresponds to 5% of the measured sensor signal for 1 ng/mL PAT, indicating that the
 304 repeatability results demonstrate satisfactory analytical performance [53, 54].

305

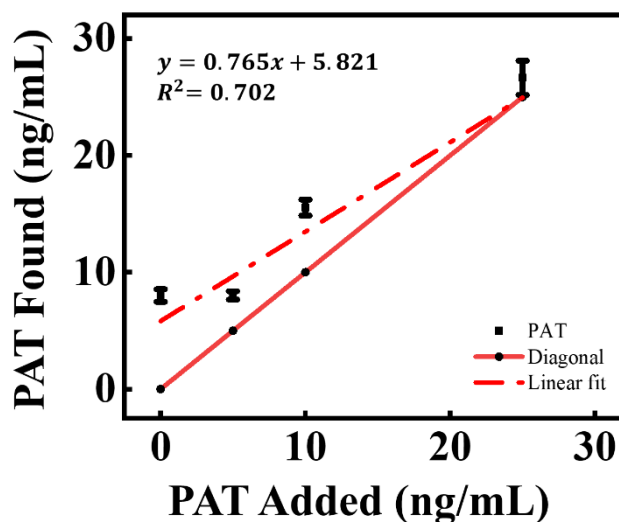

Fig. 4. Calibration curve for PAT detection of the aptasensor

The analytical parameters derived from the calibration curve are provided in Table 1. By fitting the data to the linear equation $y=0.06238[\text{PAT}]+0.94567$, which exhibits a determination coefficient R^2 of 0.94, LOD was determined using the relationship $(3.3\sigma)/\text{slope}$. Here, the maximum σ value of 0.067 μA , obtained from the measurements, was utilized. The LOD was calculated to be 3.56 ng/mL [33]. Alternatively, if the calibration curve is initiated from 2 ng/mL, the equation $y=0.05654[\text{PAT}]+1.04377$ would provide an excellent fit to the data with an R^2 value of 0.99. In this case, the calculated LOD would be 3.91 ng/mL. Notably, both LOD values are quite close to each other, indicating a negligible absolute proportional difference of approximately 9% between the sensor sensitivity (slope of the calibration curve).

Table 1. The analytical parameters for the aptasensor

Analytical parameters	Values
Linear range (ng/mL)	1 to 25
Curve equation, i (μA), [PAT] (ng/mL)	$i=0.0624[\text{PAT}]+0.9457$
Sensitivity (ng PAT/ $\mu\text{A}\cdot\text{mL}$)	0.0624
Std. error of the slope, \pm	0.0076
Std. error of the intercept, \pm	0.946
R^2	0.944
LOD ng/mL	3.56
LOQ ng/mL	10.7

Balance analysis of the model, comparison of model estimation results with actual results, change of current values for Aptamer modification time, MCH modification time and PAT incubation time, the

323 relationship of aptamer and MCH modification time with current according to RSM results, the current
324 relationship of aptamer modification PAT incubation time according to RSM results, MCH modification
325 time and current relationship of PAT incubation time according to RSM results.

326 3.3. Interference, Real Sample, and Stability Tests

327 The influence of interfering substances, OTA and ZEN, on the response of the aptasensor was
328 investigated at concentrations of 5 ng/mL and 25 ng/mL for each substance. This analysis was
329 conducted using four electrodes, and the corresponding values, obtained from the calibration curve,
330 along with the standard deviation, are depicted in Figure 5.

331
332 Fig. 5. The impact of interfering substances on the response of the aptasensor. Response at a
333 concentration of 5 ng/mL and 25 ng/mL of the interfering substance. The error bars represent the
334 standard deviations of the samples, derived from four independently prepared electrodes.

335
336 The aptamer used in this study, which specifically binds to PAT, has been previously reported in the
337 literature [50]. On the other hand, it was observed that when potential interferents including ZEN and
338 OTA were co-incubated with 5 ng/mL of PAT on the sensor surface, the measured values obtained
339 from the calibration curve exhibited a positive bias. In particular, ZEN caused a significant increase in
340 the sensor response at a concentration of 5 ng/mL, resulting in a response equivalent to
341 concentrations above 15 ng/mL. However, this non-specific interference effect was not observed at a
342 higher ZEN concentration (25 ng/mL). It is evident that, apart from the competitive interaction of ZEN
343 with the PAT-specific aptamer at low concentrations, ZEN also induces a structural interaction that
344 enhances the rate of signal decrease. The physicochemical properties of PAT, ZEN, and OTA were
345 calculated using molecular mechanics (MM2) modeling, and the results are summarized in the Table
346 S5. The calculated parameters, including LogP, total connectivity, and topological index (Wiener), differ
347 as expected for PAT, ZEN, and OTA. Although OTA is structurally closer to PAT compared to ZEN, it
348 exhibited a lower non-specific interaction with the aptamer compared to ZEN. OTA alone generated an
349 interfering signal of approximately 10% of the measured PAT concentration. When both interferents

350 interacted simultaneously, a similar positive bias of around 10% was observed. On the other hand,
351 ZEN, which is more hydrophobic compared to the others, exhibited a non-specific interaction that could
352 lead to a decrease in current through structural switching or interaction with the redox center.
353 Interestingly, this negative interaction decreased at higher ZEN concentrations. However, in this study
354 where the PAT-specific aptamer was selected and validated for different interferents, it cannot be
355 definitively concluded that the aptamer interacts non-specifically with ZEN. Instead, it can be inferred
356 that there is an interference in the aptamer switching or the interaction of the redox center with the
357 electrode surface. Nevertheless, in practical applications, since ZEN is not a contaminant in apple juice
358 [55], the mentioned interference may not significantly affect the analytical performance of the sensor.

359 In the real sample experiments, apple juice samples obtained from a local market were spiked with
360 specific concentrations of PAT using the standard addition method. The recovery percentages and real
361 sample data, expressed as the relative standard deviation (%RSD), are presented in Figure 6. The
362 results demonstrated a positive bias, with higher values obtained at lower concentrations of the added
363 PAT. Despite the linearity of the developed sensor's response to PAT, it was observed that there was
364 no inherent PAT contamination in the real samples. However, competitive interference occurred,
365 particularly at lower concentrations. Nevertheless, the high precision exhibited by repeat
366 measurements, as indicated by the low %RSD, suggested that the proposed sensor platform could be
367 directly employed for PAT detection in actual apple juice samples.

368 Moreover, the response of the sensor to the added PAT exhibited linearity, as evidenced by a R^2 of
369 0.80, albeit with a slope less than 1. This observation implies that at higher concentrations, such as the
370 recommended 25 ng/mL for the sensor platform, the discrepancy between the added PAT
371 concentration and the measured PAT response would diminish. It is important to note that the apple
372 juice samples were directly applied onto the aptasensor without any pre-treatment to extract possible
373 PAT contaminants. Despite this, the obtained standard error at the 25 ng/mL level was 6.6%, which
374 represents an acceptable level of analytical performance. Consequently, it is anticipated that the
375 suggested sensor platform can be effectively utilized for detecting PAT residues in apple juice, even at
376 the maximum allowed residue level of 50 ng/mL.

377

Fig. 6. Detected levels of PAT in apple juice using the standard addition method (two sample, N=3).

In the final phase of the study, the stability of the fabricated aptasensors was evaluated. The stability assessment relied on calculating the percentage change in the aptasensor response after a 10-day storage period at refrigeration conditions. Following the 10-day storage period, the aptasensor response exhibited a 13.12% (N = 3) positive bias relative to the initial response obtained for 5 ng/mL PAT. This observation suggests that the aptasensor maintained its performance for 10 days.

4. Conclusion

In this study, our objective was to develop a modified aptamer-based sensor for the highly selective and sensitive detection of PAT using the aptamer reported by Wu et al. [50]. The aptamer was suitably modified to enable its immobilization onto an Au-coated electrode surface, thereby facilitating the structural switching with the on-off signal capability of the sensor. MB was utilized as a modifier to facilitate the immobilization of the modified aptamer on the gold surface, ultimately leading to the development of the aptasensor.

To optimize the performance of the aptasensor, incubation durations of the aptamer, as well as the duration of the MCH and PAT incubation, were systematically investigated using the RSM method. The aim was to minimize errors and test duration. As a result, the optimal modification durations were determined as 180 minutes for the aptamer, 40 minutes for the MCH modification, and 89 minutes for the PAT incubation. The aptamer utilized in this study demonstrated the electrochemical on-off behavior of the aptasensor, where the presence of PAT induced a signal change.

The selected aptasensor exhibited a linear working range of 1-25 ng/mL, and the LOD was calculated to be 3.56 ng/mL with a 95% confidence interval determined by 3 times the standard deviation (3σ). To assess the performance of our developed aptasensor, we compared these range and LOD values with those reported in the literature for other electrochemical detection methods

403 (Table S6). The results indicated that our aptasensor holds significant potential for the accurate
404 detection of PAT.

405 In this study, we have successfully developed an electrochemical sensor based on aptamer
406 switching for the selective and sensitive detection of PAT, a mycotoxin that poses a significant concern
407 in terms of food safety. Our sensor presents several advantages compared to conventional
408 electrochemical methods for PAT detection, including a simplified assay procedure, enhanced
409 specificity, and improved sensitivity. While the developed aptasensor has demonstrated promising
410 results for the convenient and sensitive detection of PAT in buffer solutions, it is advisable to apply
411 sample pre-processing steps or utilize the aptasensor for higher concentrations (> 25 ng/mL) of PAT
412 detection in real samples. The latter recommendation is particularly relevant when analyzing apple
413 juice, where the maximum residue limit set by the authorities is 50 ng/mL.

414 In conclusion, the aptamer switching electrochemical sensor presented in this manuscript
415 represents a promising solution for PAT detection. The sensor's high sensitivity, selectivity, simplicity,
416 and potential for on-site analysis make it an attractive candidate for the mycotoxin analysis.

451 In the RSM analysis performed based on the PAT aptasensor response, the relationship of aptamer,
 452 MCH and PAT incubation times with the change in current was examined. According to the analysis
 453 results obtained as a result of the statistical evaluations, the quadratic method, which gave the best
 454 results, was recommended as the most suitable model for the experimental data. Statistical
 455 evaluations of the results obtained are given in Table S4 and their graphs are given in Figure S1.
