ABSTRACT

We present adaptive optics (AO) assisted SINFONI integral field unit (IFU) spectroscopy of eleven H α emitting galaxies selected from the High-Z Emission Line Survey (HiZELS). We obtain spatially resolved dynamics on \sim kpc-scales of star-forming galaxies (stellar mass $M_{\star} = 10^{9.5-10.5} M_{\odot}$ and star-formation rate $\text{SFR} = 2-30 M_{\odot} \text{yr}^{-1}$) near the peak of the cosmic star-formation rate history. Combining these observations with our previous SINFONI-HiZELS campaign, we construct a sample of twenty homogeneously selected galaxies with IFU AO-aided observations – the ‘SHiZELS’ survey, with roughly equal number of galaxies per redshift slice, at $z = 0.8, 1.47, \text{ and } 2.23$. We measure the dynamics and identify the major kinematic axis by modelling their velocity fields to extract rotational curves and infer their inclination-corrected rotational velocities. We explore the stellar mass Tully-Fisher relationship, finding that galaxies with higher velocity dispersions tend to deviate from this relation. Using kinemetry analyses we find that galaxy interactions might be the dominant mechanism controlling the star-formation activity at $z = 2.23$ but they become gradually less important down to $z = 0.8$. Metallicity gradients derived from the $[\text{N II}]/\text{H}\alpha$ emission line ratio show a median negative gradient for the SHiZELS survey of $\Delta \log(\text{O}/\text{H})/\Delta R = -0.026 \pm 0.008 \text{ dex kpc}^{-1}$. We find that metal-rich galaxies tend to show negative gradients, whereas metal-poor galaxies tend to exhibit positive metallicity gradients. This result suggests that the accretion of pristine gas in the periphery of galaxies plays an important role in replenishing the gas in ‘typical’ star-forming galaxies.

Key words: galaxies: abundances – galaxies: ISM – galaxies: star formation – galaxies: interactions – galaxies: evolution – galaxies: high-redshift

1 INTRODUCTION

Determining the physical processes that control star-formation and mass assembly at high redshift is an area of intense debate. At $z = 1-2$, galaxies were actively forming stars and rapidly growing their stellar mass content (e.g.

Madau et al. 1996; Sobral et al. 2009a). However, studies also found a strong decline in star formation rate (SFR) from that epoch to the present day: the cosmic star-formation rate density of the Universe has dropped by more than an order of magnitude (e.g. Karim et al. 2011; Gilbank et al. 2011; Rodighiero et al. 2011; Sobral et al. 2013b). The primary causes of the subsequent decline of the star-formation rate activity since $z = 1-2$ is still under debate.

2 *J. Molina et al.*

Two main explanations have emerged to explain how galaxies maintained such high levels of star formation at those redshifts: (1) the rate of mergers and tidal interactions may have been higher at that epoch, driving quiescent disks into bursts of star-formation (e.g. [Bridge et al. 2007](#); [Conselice 2009](#)); and (2) galaxies were continuously fed gas from the inter-galactic medium (IGM), promoting and maintaining star-formation activity driven by internal dynamical processes within the inter-stellar medium (ISM; e.g. [Keres et al. 2005](#); [Bournaud et al. 2007](#); [Dekel et al. 2009a](#)).

To test the predictions from these galaxy evolution models, a method for distinguishing between mergers and galaxy disks needs to be implemented. Three main methods of estimating the merger fraction are: counting close pairs of galaxies, assuming that they will subsequently merge (e.g. [Lin et al. 2008](#); [Bluck et al. 2009](#)); using a method of identifying galaxies with merging morphology (e.g. [Conselice 2003, 2008, 2009](#); [Lotz et al. 2008](#); [Stott et al. 2013a](#)); and employing detailed integral field unit (IFU) spectroscopy to look for dynamical merger signatures (e.g. [Shapiro et al. 2008](#); [Förster Schreiber et al. 2009](#); [Bellocchi et al. 2012](#); [Contini 2012](#); [Swinbank et al. 2012a](#)).

If secular processes drive the galaxy disks evolution, we need to measure the internal dynamical properties of galaxies at the peak epoch of the volume-averaged SFR, constrain how the structural properties of galaxy disks have varied over cosmic time and test if the prescriptions developed to understand the star-formation processes at $z = 0$ are still valid in the ISM of galaxies at high- z .

Taking advantage of integral field unit (IFU) adaptive optics assisted observations, significant effort has been invested to measure the kinematics of the gas within star-forming galaxies at $z \sim 1 - 2$ in order to test competing models for galaxy growth (see review by [Glazebrook 2013](#)). Previous observations have shown highly turbulent, rotationally supported disks with clumpy star-formation and large gas fractions ($f_{\text{gas}}=20-80\%$; [Elmegreen et al. 2009](#); [Förster Schreiber et al. 2009](#); [Genzel et al. 2010](#); [Geach et al. 2011](#); [Wisnioski et al. 2011](#); [Swinbank et al. 2012b](#); [Stott et al. 2016](#)). Higher gas fractions might lead the formation of massive ($\sim 10^9 M_{\odot}$) clumps by gravitational fragmentation of dynamically unstable gas ([Escala & Larson 2008](#)). The typical rotation velocities of these systems are $100 - 300 \text{ km s}^{-1}$, so very similar to local galaxies ([Cresci et al. 2009](#); [Gnerucci et al. 2011b](#); [Vergani et al. 2012](#); [Swinbank et al. 2012a](#)), but the typical velocity dispersion values range from 50 to 100 km s^{-1} ([Förster Schreiber et al. 2006](#); [Genzel et al. 2006](#)). This means a circular velocity to velocity dispersion ratio (V/σ) range from 1 to 10 at $z \sim 2$ ([van Starkenburg et al. 2008](#); [Law et al. 2009](#); [Förster Schreiber et al. 2009](#); [Gnerucci et al. 2011b](#); [Genzel et al. 2011](#); [Stott et al. 2016](#)). By comparison, the Milky Way and other similar thin disks galaxies at low- z have $V/\sigma \sim 10 - 20$ ([Epinat et al. 2010](#); [Bershady et al. 2010](#)). This suggests that the gas dynamics of high- z galaxies are not just dominated by ordered rotation or random motions, but by a contribution from both.

If the structural properties of galaxy disks have varied over cosmic time, we would expect to see evidence in kinematic scaling relations. For example, one potential evidence would be an evolution of the Tully-Fisher relationship ([Tully & Fisher 1977](#)), which describes the interdependence of baryonic and dark matter in galaxies by studying the evo-

lution of the stellar luminosity (M_{B}) versus circular velocity. It traces a simple means of the build-up of galaxy disks at different epochs. Since the B -band luminosity is sensitive to recent star formation, attempts have also been made to measure the evolution of the stellar mass (M_{\star}) Tully-Fisher relation which reflects the relation between the past-average star-formation history and halo mass. In particular, hydrodynamic models suggest that the zero-point of the stellar mass Tully-Fisher relationship should evolve by ~ -1.1 dex at fixed circular velocity between $z = 0 - 2$ ([McCarthy et al. 2012](#)). At a given rotational velocity, the stellar mass in a high- z disk galaxy should be smaller than a low- z disk galaxy as star-formation builds it up. Substantial efforts have been made in order to measure the Tully-Fisher relationship at redshift $z = 1 - 2$ ([Cresci et al. 2009](#); [Förster Schreiber et al. 2009](#); [Gnerucci et al. 2011b](#); [Miller et al. 2011, 2012](#); [Swinbank et al. 2012a](#); [Sobral et al. 2013b](#); [Di Teodoro et al. 2016](#); [Tiley et al. 2016](#)). Recently [Tiley et al. \(2016\)](#) have measured a stellar-mass TFR zero-point evolution of -0.41 ± 0.08 dex for rotationally supported galaxies defined with $V/\sigma > 3$ from the ‘KMOSS Redshift One Spectroscopic Survey’ (KROSS; [Stott et al. 2016](#)). However, they measure no significant offset in the absolute rest-frame K -band TFR (M_K -TFR) over the same period. This excess of K -band luminosity at fixed stellar mass measured from the high- z galaxies could be explained by considering their higher SFRs in comparison with their local Universe counterparts at same stellar mass. The excess of light that comes from young stars decreases the mass-to-light ratio in high- z galaxies decoupling the evolution of both, the M_K -TFR and the M_{\star} -TFR.

If the Tully-Fisher relationship evolves with redshift, then it would be expected that the galaxy size-velocity relation also evolves ([Dutton et al. 2011b](#)). In a Λ CDM cosmology, the sizes of galaxy disks and their rotational velocities should be proportional to their parent dark matter halos, and since the halos are denser at high- z for a fixed circular velocity, then disk sizes should scale inversely with Hubble time ([Mo et al. 1998](#)). The evolution of the size-velocity relation has been observed ([Swinbank et al. 2012a](#)), but increasing the number statistics should be helpful in order to overcome random errors due to different methods and conversions of size measurements.

A third potential observational tool to constrain galaxy evolution models is the measure of the chemical abundance within galaxies using a simple disk model. If the gas accretion in high-redshift galaxies is via accretion of pristine gas from the IGM along filaments onto the galaxy disk at $10-20 \text{ kpc}$ from the galaxy centre, then the inner disks of galaxies should be enriched by star-formation and supernovae whilst the outer-disk is continually diluted by pristine material, leaving strong negative abundance gradients ([Dekel et al. 2009a,b](#)). This gradient would flatten if the IGM gas is redistributed, e.g. via merger interactions.

To chart the evolution of star-forming galaxies with cosmic time, we exploit the panoramic (degree-scale) High- Z Emission Line Survey (HiZELS). This survey targets $\text{H}\alpha$ emitting galaxies in four precise ($\delta z=0.03$) redshift slices: $z = 0.4, 0.8, 1.47$ and 2.23 ([Geach et al. 2008](#); [Sobral et al. 2009a, 2010, 2011, 2012, 2013b](#)). This survey provides a large luminosity-limited sample of homogeneously selected $\text{H}\alpha$ emitters at the cosmic star-formation density peak epoch,

SHiZELS Survey: \sim kpc-scale spectroscopy of ‘typical’ star-forming galaxies at $z = 0.8 - 2.2$ 3

Figure 1. The relation between specific star formation rate (sSFR) and stellar mass for the HiZELS survey (grey dots; Sobral et al. 2013a, 2014), Swinbank et al. (2012a)’s sample (circles with X) and our sample (filled circles). We colour-coded our sample and the Swinbank et al. (2012a) sample by redshift. The sky blue, blue and dark blue colours represent the sources at $z = 0.8, 1.47, 2.23$ respectively. The filled squares represents the median values per redshift. The black dotted line shows the $\text{sSFR} = 10^{-9} \text{ yr}^{-1}$ value. The colour-coded dashed lines represent the location of the ‘main sequence’ of star-forming galaxies at each redshift slice from Karim et al. (2011) demonstrating that our sample and Swinbank et al. (2012a)’s sample are ‘typical’ for each epoch.

and provides a powerful resource for studying the properties of starburst galaxies and the star-forming galaxies that shows a tight dependence of SFR on stellar mass, the so-called ‘main-sequence’ of star-forming galaxies (Noeske et al. 2007; Pannella et al. 2009; Elbaz et al. 2011). Most of the HiZELS galaxies will likely evolve into $\sim L^*$ galaxies by $z = 0$ (Sobral et al. 2011), but are seen at a time when they are assembling most of their stellar mass, and thus are seen at a critical stage in their evolutionary history.

In this paper, we present adaptive optics assisted integral field spectroscopy with SINFONI, yielding $\sim 0''.15$ resolution (\sim kpc scale), of eleven star-forming galaxies selected from the HiZELS survey in three redshift slices, $z = 0.8, 1.47$ and 2.23 (Sobral et al. 2013a). The HiZELS survey is based on observations obtained using the Wide Field Camera (WFCAM) on the 3.8-m United Kingdom Infrared Telescope (UKIRT; Geach et al. 2008; Sobral et al. 2009a). Combined with nine targets from a previous similar SINFONI campaign (Swinbank et al. 2012a,b) our study present one of the largest samples of homogeneously selected high-redshift star-forming galaxies with AO-aided resolved dynamics, star-formation and chemical properties. Throughout the paper, we assume a Λ CDM cosmology with $\Omega_{\Lambda} = 0.73$, $\Omega_{\text{m}} = 0.27$, and $H_0 = 72 \text{ km s}^{-1} \text{ Mpc}^{-1}$, so at redshift $z = 0.8, 1.47$ and 2.23 , a spatial resolution of $0''.1$ corresponds to a physical scale of $0.74, 0.84$ and 0.82 kpc respectively.

2 SAMPLE SELECTION, OBSERVATIONS & DATA REDUCTION

2.1 HiZELS

To select the targets for IFU observations, we exploited the large sample of sources from the HiZELS imaging of the

COSMOS, SA22 and UDS fields (Best et al. 2013; Sobral et al. 2013b, 2015, 2016a) to select $\text{H}\alpha$ emitters sampling the so called ‘main-sequence’ at $z = 0.8 - 2.23$ (Fig. 1). Taking the advantage of the large sample we could select galaxies which lie close ($< 30''$) to bright ($R < 15.0$) stars, such that natural guide star adaptive optics correction (NGS correction) could be applied to achieve high spatial resolution. For this programme we selected eighteen galaxies with stellar mass between $M_* = 10^{9.5-10.5} M_{\odot}$ and $\text{H}\alpha$ fluxes greater than $f_{\text{H}\alpha} \geq 0.7 \times 10^{-16} \text{ erg s}^{-1} \text{ cm}^{-2}$ to ensure that their star-formation properties and dynamics could be mapped in a few hours. Out of the eighteen galaxies observed with SINFONI, we detect eleven of them with high enough signal-to-noise (S/N). Given the significant sky-noise in near-IR spectra, source detection was optimally performed by detailed visual inspection of dynamical and line width features within the data-cubes (using Interactive Data Language and QFitsView). Although the rate of detection of bright $\text{H}\alpha$ emitters derived from our sample may seem modest ($\sim 60\%$), it is comparable with the detection rate derived from the previous SINFONI campaign ($\sim 65\%$; Swinbank et al. 2012a). We note that both samples were drawn from the same HiZELS survey. We note, however, that the detection rate derived from the non-AO KROSS survey (using KMOS; Stott et al. 2016) –which was also drawn from the HiZELS survey at $z \sim 0.8$ – is nearly $\sim 92\%$. This suggest that the modest rate of detection derived from our sample and the previous SINFONI campaign might be inherent to the AO-observations.

2.2 SINFONI Observations

To measure the dynamics of our sample from the nebular $\text{H}\alpha$ emission line, we used the SINFONI IFU (Eisenhauer et al. 2003) on the ESO VLT (Project 092.A-0090(A); P.I.E.Ibar). We use the $3'' \times 3''$ field of view at spatial resolution of $0''.1 \text{ pixel}^{-1}$. At $z = 0.8, 1.47$ and 2.23 the $\text{H}\alpha$ emission line is redshifted to $\sim 1.18, 1.61$ and $2.12 \mu\text{m}$ and into the J, H and K -bands respectively. The spectral resolution in each band is $\lambda/\Delta\lambda \sim 3700$, and sky OH lines are considerably narrower ($\sim 4\text{\AA}$ full width half maximum – FWHM) compared to the galaxy line widths. We use a NGS correction since each target is close to a bright guide star.

The observational setup for these targets was done in the same manner as in Swinbank et al. (2012a). To observe the targets we used ABBA chop sequences (OBs with individual exposures of 600 seconds), nodding $1''.6$ across the IFU. In order to achieve higher signal to noise ratios on sources at higher redshifts we used 2, 3, 4 OB’s for the $z = 0.8, 1.47, 2.23$ samples implying a total observing time of 4.8, 7.2, 9.6 ks respectively. The observations were carried between 2013 October 27 and 2014 September 3 in $\sim 0''.8$ seeing and photometric conditions. The median Strehl achieved for our observations is 33% (Table 1).

Individual exposures were reduced using the SINFONI ESOREX data reduction pipeline which extracts flat-fields, wavelength calibrates and forms the data-cubes for each exposure. The final data-cube was generated by aligning manually the individual OBs on average (shifting them by $\lesssim 0''.2 \sim 2 \text{ pix}$) and then combining these using a sigma-clipping average at each pixel and wavelength. This min-

Table 1. Flux densities ($f_{H\alpha}$) are taken from narrow-band photometry and include contamination by [N II]. SFR $_{H\alpha}^{\text{obs}}$ are not corrected for extinction. $r_{1/2}$ is the H α half-light radius and has been deconvolved by the PSF.

imised the effect of the OH emission/absorption features seen in the final data-cube.

2.3 Stellar Masses

Stellar masses are computed by fitting SEDs to the rest-frame UV, optical and near-infrared data available (*FUV, NUV, U, B, g, V, R, i, I, z, Y, J, H, K*, 3.6, 4.5, 5.8 and 8.0 μm collated in Sobral et al. 2014, and references therein), following Sobral et al. (2011). The SED templates were generated with the Bruzual & Charlot (2003) package using Bruzual (2007) models, a Chabrier (2003) IMF and an exponentially declining star formation history with the form $e^{-t/\tau}$, with τ in the range 0.1–10 Gyr. The SEDs were generated for a logarithmic grid of 200 ages (from 0.1 Myr to the maximum age at each redshift being studied). Dust extinction was applied to the templates using Calzetti et al. (2000) extinction law with $E(B-V)$ in the range 0 to 0.5 (in steps of 0.05) roughly corresponding to a H α extinction $A_{H\alpha} \sim 0-2$ mag. The models are generated with different metallicities, including solar (Sobral et al. 2011). For each source, the stellar mass and the dust extinction are computed as the median values of the 1σ best fits over the range of parameters (see Table 1).

2.4 Star-Formation Rates

The star-formation rates of the sample are measured from the H α emission line flux calculated from the HiZELS survey. Adopting the Kennicutt (1998) calibration and assuming a Chabrier IMF, the SFRs are given by $\text{SFR}_{H\alpha}^{\text{obs}} (M_{\odot} \text{ yr}^{-1}) = 4.6 \times 10^{-42} L_{H\alpha}^{\text{obs}} (\text{erg s}^{-1})$. At the three redshift ranges of our sample, the average H α fluxes of our galaxies correspond to SFRs (uncorrected for extinction) of $\text{SFR}_{H\alpha}^{\text{obs}} (M_{\odot} \text{ yr}^{-1}) \approx 3, 6$ and $21 M_{\odot} \text{ yr}^{-1}$ at $z = 0.8, 1.47$ and 2.23 respectively. The median $E(B-V)$ for our sample is $E(B-V) = 0.2 \pm 0.1$ (see Table 1), which correspond to $A_{H\alpha} = 0.79 \pm 0.16$ ($A_V = 0.96 \pm 0.20$). This suggests reddening corrected star-formation rates of $\text{SFR}_{H\alpha}^{\text{corr}} (M_{\odot} \text{ yr}^{-1}) \approx 6,$

13 and $43 M_{\odot} \text{ yr}^{-1}$ at $z = 0.8, 1.47$ and 2.23 respectively. Hereafter, we use an extinction value of $A_{H\alpha} = 1.0$ mag as used in previous works based on the HiZELS survey (e.g. Sobral et al. 2012, Stott et al. 2013b, Ibar et al. 2013, Thomson et al. submitted) in order to compare consistently.

2.5 Spatial extent

To measure the spatial extent of the galaxy, we calculate the half-light radii ($r_{1/2}$). Those are calculated from the collapsed continuum subtracted cubes, where the encircled H α flux decays to half its total integrated value. The total integrated value is defined as the total H α luminosity within a Petrosian radius. We adopted the ‘Sloan Digital Sky Survey’ (SDSS) Petrosian radius definition with $R_{p,\text{lim}} = 0.2$. We account for the ellipticity and position angle of the galaxy obtained from the best-fit disk model (see §3). The $r_{1/2}$ errors are derived by bootstrapping via Monte-Carlo simulations the errors in measured emission line intensity and estimated dynamical parameters of each galaxy. The half-light radii are corrected for beam-smearing effects by subtracting the seeing (0.15'') in quadrature. The median $r_{1/2}$ for our sample is found to be 2.4 ± 0.1 kpc (Table 1), which is consistent with previous studies at similar redshift range (Swinbank et al. 2012a).

2.6 Average ISM properties

To analyse the H α and [N II] line fluxes for our targets we first collapse each data-cube into a one-dimensional spectrum (see Fig. 2). In eight cases we detect the [N II] $\lambda 6583$ emission line, deriving a median ratio of $[\text{N II}]/\text{H}\alpha = 0.27 \pm 0.02$, with a range between $0.10 < [\text{N II}]/\text{H}\alpha < 0.43$ (Table 1). None of the galaxies display strong active galactic nucleus (AGN) signatures in their rest-frame optical spectra (Fig. 2).

To search for fainter lines and obtain the mean properties of our observed sample we de-redshift each spectrum to rest-frame and co-add them (weighted by flux), yielding the composite spectrum shown in Fig. 2. Weighting by

Figure 2. Spatially integrated one dimensional spectra around the redshifted $H\alpha$ emission for each of the galaxies in our sample. $H\alpha$, $[N\text{ II}]\lambda\lambda 6583,6548$ and $[S\text{ II}]\lambda\lambda 6716,6731$ emission lines are represented by the red-dashed lines. We detect $[N\text{ II}]$ emission in eight targets within our sample and the median $[N\text{ II}]/H\alpha$ for the sample is 0.27 ± 0.02 , with a range of $0.10 < [N\text{ II}]/H\alpha < 0.43$. None of the galaxies display strong AGN signatures in their near-infrared spectra (e.g. broad lines or high $[N\text{ II}]/H\alpha$ ratios).

flux instead of signal-to-noise helps to smooth residual features seen in low S/N spectra (e.g. SA22-54, UDS-17 in Fig. 2). In this stacked spectrum, we measure a $[N\text{ II}]/H\alpha$ ratio of 0.25 ± 0.04 which is consistent with the median ratio derived for our sample. We also make a weak detection of the $[S\text{ II}]\lambda\lambda 6716,6731$ doublet and derive a flux ratio of $I_{6716}/I_{6731} = 1.04 \pm 0.31$. If we assume a typical $H\text{ II}$ region temperature of 10^4 K , then the measured I_{6716}/I_{6731} ratio corresponds to an electron density in the range of $100\text{--}1000\text{ cm}^{-3}$ (Osterbrock et al. 1989), and an upper limit to the ionised gas mass in the ISM of $4\text{--}40 \times 10^{10} M_{\odot}$ for a disk galaxy with half-light radius of $\sim 2.4\text{ kpc}$ (Table 1). For an isobaric density distribution of the ionized gas, the density is defined in terms of the mean ISM pressure P and mean electron temperature ($T_e \sim 10^4\text{ K}$), through $P/k_B \sim T_e n_e$. Therefore we estimate a median ISM pressure of $P/k_B \sim 10^{6-7}\text{ K cm}^{-3}$ which is $\sim 100\text{--}1000$ times higher than the typical ISM pressure in the Milky Way ($\sim 10^4\text{ K cm}^{-3}$) and consistent with other high- z galaxy ISM pressure estimates (Swinbank et al. 2015). Although this value has considerable uncertainty, the derived pressure is compatible with hydrodynamic models which suggest that typical pressure in the ISM of star-forming galaxies should increase from $\sim 10^4\text{ K cm}^{-3}$ at $z = 0.1$ to $\sim 10^{6-7}\text{ K cm}^{-3}$ at $z = 2$ (Crain et al. 2015). The $I_{6716}/H\alpha$ flux ratio reflects the ionisation strength of the ISM. We measure $I_{6716}/H\alpha = 0.12 \pm 0.03$. Considering also the derived $[N\text{ II}]/H\alpha$ flux ratio, then we suggest an ionisation parameter of $\log_{10}(U/\text{cm}^3) = -3.6 \pm 0.3$ (Osterbrock et al. 1989; Collins & Rand 2001). Those median values are in agreement with Swinbank et al. (2012a), Stott et al. (2013a) and Sobral et al. (2013a, 2015).

2.7 Galaxy Dynamics

To measure the dynamics of each galaxy, we fit the $H\alpha$ and $[N\text{ II}]\lambda\lambda 6548,6583$ emission lines pixel-by-pixel. Following Swinbank et al. (2012a) we use a χ^2 minimisation procedure, estimating the noise per spectral channel from an area that does not contain source emission. We first attempt to identify a $H\alpha$ line in each $0''.1 \times 0''.1$ pixel ($\sim 1 \times 1\text{ kpc}$, which corresponds to the approximate PSF), although if the fit fails to detect the emission line, the area is increased by considering the neighbouring pixels, for example using the averaged signal from an area of 3×3 pixels. We use the criterion that the fit requires a $S/N > 5$ to detect the emission line in each pixel, and when this criterion is met then we simultaneously fit the $H\alpha$ and $[N\text{ II}]\lambda\lambda 6548,6583$ emission allowing the centroid, intensity and width of the Gaussian profile to vary (the FWHM of the $H\alpha$ and $[N\text{ II}]$ lines are coupled in the fit).

Even at \sim kpc-scale resolution, there is a contribution to the line widths of each pixel from the large-scale velocity motions across the galaxy, which must be corrected for (Davies et al. 2011). This is calculated for each pixel where the $H\alpha$ emission is detected. We calculate the local luminosity-weighted velocity gradient (ΔV) across the PSF (ΔR) and subtract this from the measured velocity dispersion (see Stott et al. 2016 for more details). We show the $H\alpha$ intensity, velocity and line of sight velocity dispersion maps in Fig. 3 for our sample.

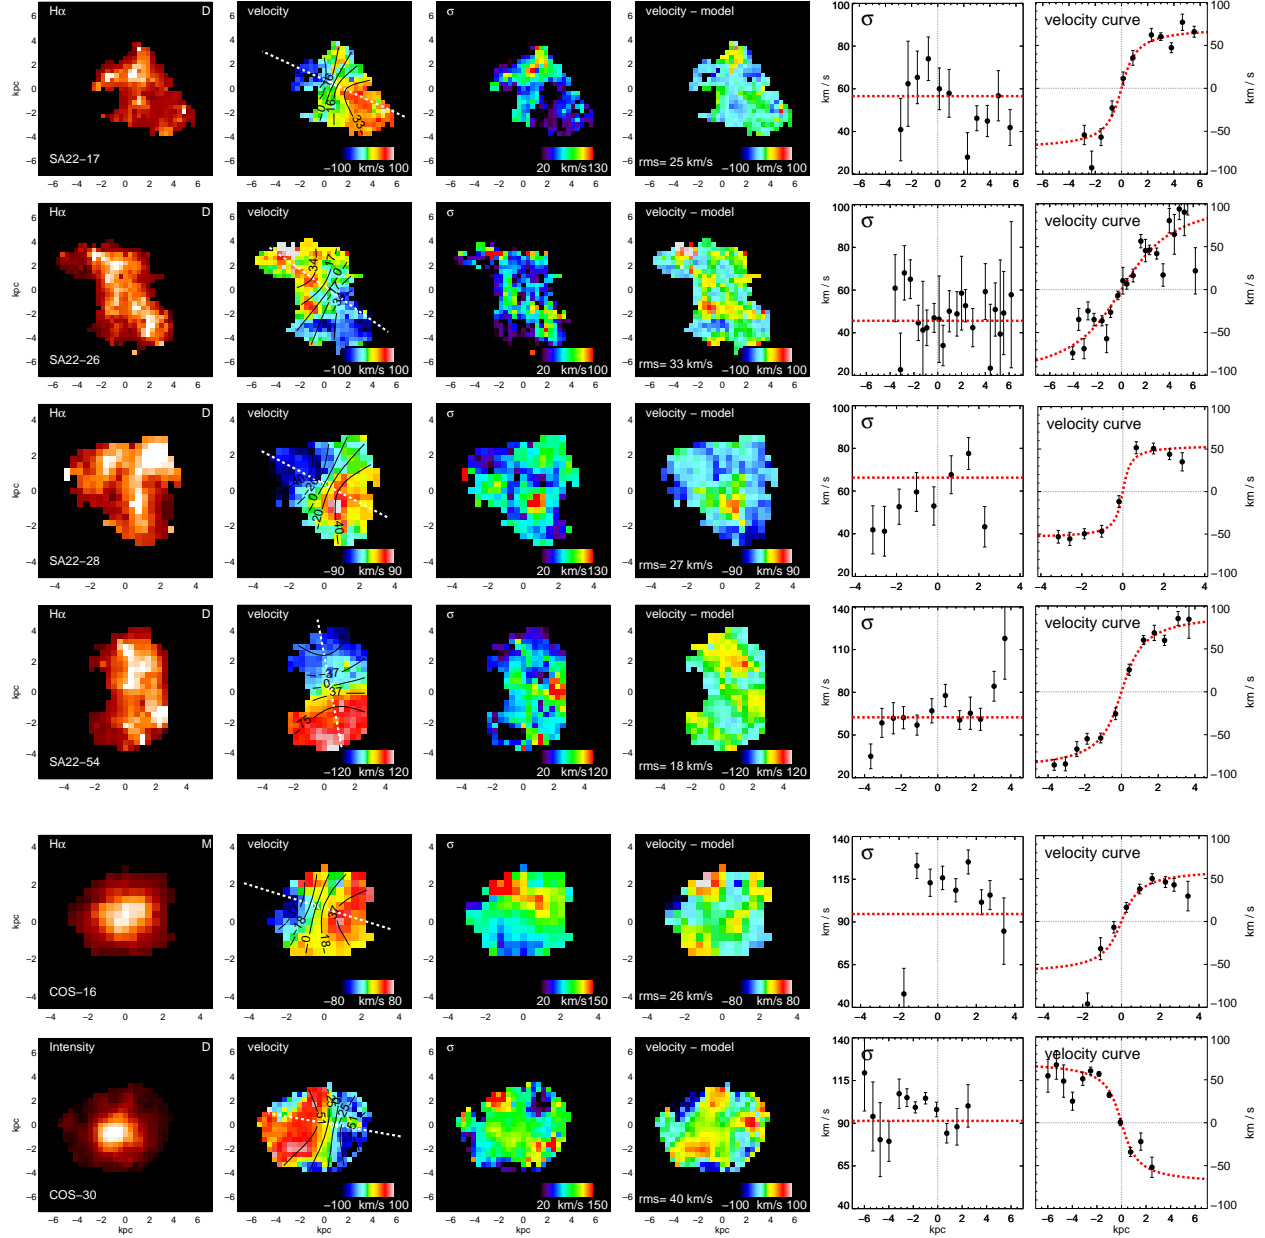

6 *J. Molina et al.*

Figure 3. $H\alpha$ intensity, velocity, line-of-sight velocity dispersion (σ), residual fields, one dimensional velocity dispersion profile and one dimensional velocity profile (columns) for eleven galaxies from our observed sample (rows). The $H\alpha$ intensity map also shows the classification done by kinemetry analysis (see §3): six galaxies were classified as disks (D), four as mergers (M) and one as unresolved/compact (C). The unresolved/compact source (SA22-01) have no modelling. The velocity field has overlotted the kinematical centre, the major kinematic axis and velocity contours of the best-fit two dimensional kinematical disk model. The line-of-sight velocity dispersion (σ) field is corrected for the local velocity gradient ($\Delta V/\Delta R$) across the PSF. The residual map is constructed by subtracting the best-fit kinematic model from the velocity map: the root-mean-square (r.m.s) of these residuals are given in each panel. The one dimensional velocity profiles are derived from the two dimensional velocity field using the best-fit kinematical parameters and a slit width of ~ 1 kpc across the major kinematic axis. The error bars shows the 1σ uncertainty. In the velocity dispersion profile plots, the red-dashed line shows the mean galactic velocity dispersion value. The dotted grey line represents the best-fit dynamical centre (Table 2). In the last column, the red-dashed line show the best one-dimensional fit using an arctan model for each source. The dotted vertical and horizontal grey lines represent the best-fit dynamical centre and the zero velocity point respectively.

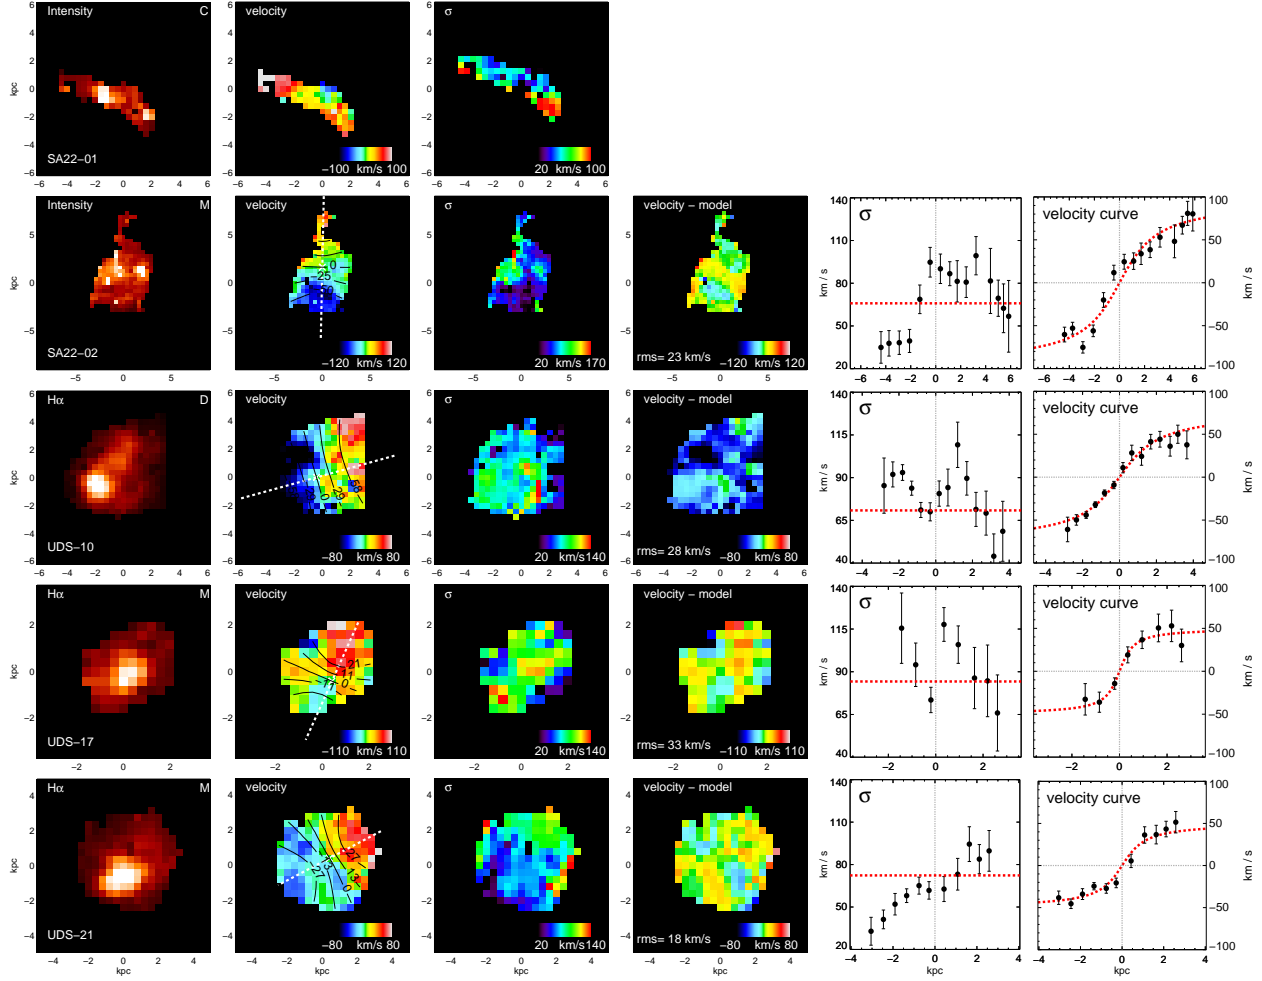

SHiZELS Survey: $\sim kpc$ -scale spectroscopy of ‘typical’ star-forming galaxies at $z = 0.8 - 2.2$ 7

Figure 3. Continued.

TABLE 2: DYNAMICAL PROPERTIES

ID	inc. (deg)	σ (km/s)	V_{asym} (km/s)	$V_{2.2}$ (km/s)	χ^2_{ν}	K_{Tot}	Class

Table 2. Dynamical properties of the galaxies in our sample. ‘inc.’ is the inclination angle defined by the angle between the line of sight and the plane of the galaxy disk (for a face-on galaxy, $\text{inc} = 0$ deg.). σ is the average velocity dispersion across the galaxy image corrected for “beam smearing” effects due to PSF; see §2.7. V_{asym} and $V_{2.2}$ are inclination corrected. The χ^2_{ν} of the best two-dimensional fit for each source is given in column six. K_{Tot} is the kinematics coefficient. The classes in the final column denote Disk(D), Merger(M) and Compact(C) (see §3 for more details of these parameters).

3 ANALYSIS, RESULTS & DISCUSSION

In Fig. 3 we can see a variety of H α structures, including various levels of clumpiness of the emission within our sample. However we note that resolution effects tend to smooth kinematic deviations making galaxy velocity fields appear more disky than they actually are (Bellocchi et al. 2012). Fig. 3 also shows that there are strong velocity gradients in many cases (e.g. SA22-28, SA22-54) with peak-to-peak differences ($V_{\max} \sin(i)$) ranging from 90–180 km s $^{-1}$ and ratio of peak-to-peak difference to line-of-sight velocity dispersion (σ) of $V_{\max} \sin(i)/\sigma = 1.1$ –3.8. This is in concordance with previous observations of galaxies at $z \sim 2$ (van Starckenburg et al. 2008; Law et al. 2009; Förster Schreiber et al. 2009; Gnerucci et al. 2011b; Genzel et al. 2011). Assuming that the dynamics of the underlying mass distribution are coupled to the measured kinematics of the ionized gas, then these observed high- z galaxies are consistent with highly turbulent systems.

Although a ratio of $V_{\max}/\sigma = 0.4$ has been used to crudely differentiate rotating systems from mergers (Förster Schreiber et al. 2009), more detailed kinematic modelling is essential to reliably distinguish these two populations. We therefore attempt to model the two-dimensional velocity field by first identifying the dynamical centre and the kinematic major axis. We follow Swinbank et al. (2012a) to construct two-dimensional models with an input rotation curve following an arctan function ($V(r) = \frac{2}{\pi} V_{\text{asym}} \arctan(r/r_t)$), where V_{asym} is the asymptotic rotational velocity and r_t is the effective radius at which the rotation curve turns over (Courteau 1997). This model has six free parameters (V_{asym} , r_t , $[x/y]$ centre, position angle (PA) and disk inclination) and a genetic algorithm (Charbonneau 1995) is used to find the best fit (see Swinbank et al. 2012a for more details). The best-fit kinematics maps and velocity residuals are shown in Fig. 3, the best-fit inclination and disk rotation speeds are given in Table 2. The mean deviation from the best-fit models within the sample (indicated by the typical RMS) is $\langle \text{data} - \text{model} \rangle = 27 \pm 2 \text{ km s}^{-1}$ with a range of $\langle \text{data} - \text{model} \rangle = 18$ –40 km s $^{-1}$. These offsets are probably the product of an un-relaxed dynamical component indicated by the high mean velocity dispersion $\sigma = 71 \pm 1 \text{ km s}^{-1}$ of our sample (Table 2), dynamical substructures, or effects of gravitational instability within the disk.

We use the dynamical centre and position angle derived from the best-fit dynamical model to extract the one-dimensional rotation curve across the major kinematic axis of each galaxy (see Fig. 3). Three targets (SA22-26, SA22-54 and SA22-02) do not show a flattening of the velocity curve at large radii, so V_{asym} can only be estimated using an extrapolation of the true rotational velocity for these targets.

In order to distinguish between rotation and motion from disturbed kinematics we use ‘kinemetry’ which measures the asymmetry of the velocity field and line-of-sight velocity dispersion maps for each galaxy (Shapiro et al. 2008). This technique has been well calibrated and tested at low redshift (e.g. Krajnović et al. 2006), whilst at high redshift it has been used to determine the strength of deviations of the observed velocity and dispersion maps from an ideal rotating disk (Alaghband-Zadeh et al. 2012; Shapiro et al. 2008; Sobral et al. 2013a; Swinbank et al. 2012a). Briefly, kinemetry proceeds to analyse the two dimensional velocity and veloc-

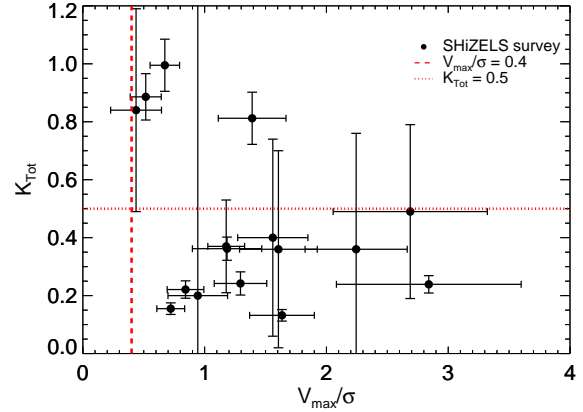

Figure 4. The kinematic measure K_{Tot} (see §3) against the V_{\max}/σ ratio for the SHIZELS Survey. The red-dashed line shows the $V_{\max}/\sigma = 0.4$ ratio which has been used to crudely differentiate rotating systems from mergers (Förster Schreiber et al. 2009). The red-dotted line shows the $K_{\text{Tot}} = 0.5$ value which is used to distinguish between galaxy disks from mergers (Shapiro et al. 2008). Although there is no strong correlation between both quantities, it is notable that galaxies classified as mergers by kinemetry criterion tend to show lower V_{\max}/σ ratio, however not as low as 0.4. This suggests that the $V_{\max}/\sigma = 0.4$ criterion tend to underestimate the total number of mergers in a given galaxy sample.

ity dispersion maps using azimuthal kinematic profiles in an outward series of best fitting elliptical rings. The kinematic profile as a function of angle is then expanded harmonically, which is equivalent to a Fourier transformation which has coefficients k_n at each tilted ring (see Krajnović et al. 2006 for more details).

Defining the velocity asymmetry (K_V) and the velocity dispersion asymmetry (K_σ) using the eigen k_n coefficients from the velocity and velocity dispersion maps respectively, we measure the level of asymmetries from an ideal disk in our galaxies (we omit SA22-01 from this analysis as it is not well-resolved). For an ideal disk, the values K_V and K_σ will be zero. In a merging system, strong deviations from the idealised case produces large K_V and K_σ values. The total asymmetry is defined as $K_{\text{Tot}}^2 = K_V^2 + K_\sigma^2$ and we use this quantity to differentiate disks ($K_{\text{Tot}} < 0.5$) from mergers ($K_{\text{Tot}} > 0.5$) following Shapiro et al. (2008). The K_{Tot} errors are derived by bootstrapping via Monte-Carlo simulations the errors in measured velocities, velocity dispersions, and estimated dynamical parameters of each galaxy.

Bellocchi et al. (2012) proposed a modified kinemetry criterion ($K_{\text{Tot},B12}$), which try to distinguish between post-coalescence mergers and disks. As the major merger evolves, the central region tends to relax rapidly into a disk meanwhile the outer parts remain out of equilibrium. Therefore the outer regions retain better the memory of a merger event (Kronberger et al. 2007). In order to consider this effect, Bellocchi et al. (2012) weights more highly the outskirts of each galaxy when combining the asymmetries measured from the velocity and velocity dispersion maps.

These two kinemetry criteria have been compared with a visual classification scheme done at higher spatial resolution. Hung et al. (2015) observed eighteen (U)LIRGs at $z < 0.088$ with the *Hubble Space Telescope* (HST) Ad-

vanced Camera for Surveys (ACS) and considered another six sources from the Digitized Sky Survey (DSS). They classified galaxies by inspecting their optical morphologies (Larson et al. 2016) and then they obtained IFS data for this sample from the Wide Field Spectrograph (WiFeS). They artificially redshifted their local IFS observations to $z = 1.5$ to make a comparison with IFU seeing-limited observations ($0''.5$) at high- z . Hung et al. (2015) concluded that Shapiro et al. (2008)’s kinemetry criterion (K_{Tot}) tend to underestimate the merger fraction whereas Bellocchi et al. (2012)’s kinemetry criterion ($K_{\text{Tot,B12}}$) overestimated the number of mergers within the same sample. Hereafter, we will use the kinemetry criterion defined by Shapiro et al. (2008) to classify our targets, considering that our merger fraction values are likely to be lower limits at each redshift.

From the kinemetry criterion, we classify four targets as merger systems and six targets as rotating systems (see Table 2). In addition, from the kinemetry criterion error rate (see Shapiro et al. 2008 for more details), we expect that ~ 1 merger is being misclassified as a disk and ~ 1 disk is being misclassified as merger. The fraction of rotating systems within our sample is $\sim 60\%$, which is consistent within 1σ with that found from other $H\alpha$ IFU surveys at similar high redshift (e.g. Förster Schreiber et al. 2009; Jones et al. 2010b; Wisnioski et al. 2011; Swinbank et al. 2012a). We note that most of our mergers are identified in galaxies at $z \sim 2.23$ and the large error estimates are inherent of the low statistics of our sample.

In Fig. 4 we plot the K_{Tot} parameter against the V_{max}/σ ratio for our sample and that presented by Swinbank et al. (2012a). All of these galaxies were observed at \sim kpc-scale resolution using AO. We find no correlation between both quantities. Although galaxies classified as mergers by kinemetry tend to lie in the region with lower V_{max}/σ ratio, we find that the $V_{\text{max}}/\sigma = 0.4$ merger criterion is not consistent with the more sophisticated kinematic estimate K_{Tot} , suggesting that the former criterion under-estimates the total number of mergers within a given galaxy sample. This also suggests that a detailed kinematic analysis is needed in order to classify mergers from galaxy disks.

Hereafter, we will refer to the ‘SHiZELS’ survey as the compilation of the observations presented in this work with the previous observations by Swinbank et al. (2012a). In this previous campaign they observed nine $H\alpha$ -selected star-forming galaxies between $z = 0.84 - 2.23$ with SINFONI. This sample was also drawn from the HiZELS survey. The median M_* and SFR are $\sim 2 \times 10^{10} M_{\odot}$ and $\sim 7 M_{\odot} \text{ yr}^{-1}$ respectively (see Swinbank et al. 2012a for more details).

3.1 The Stellar-Mass Tully-Fisher and $M_*-S_{0.5}$ Relations

The Tully-Fisher relation (TFR) is a fundamental scaling relation describing the interdependence of luminosity or stellar mass and the maximum rotational velocities (a dark matter mass tracer) in galaxies. It allows us to trace the evolution of the mass-to-luminosity ratio of populations of galaxies at different epochs. Recently the KROSS survey (Stott et al. 2016; Tiley et al. 2016; Harrison et al. submitted) have provided a new perspective on TFR evolution by observing ~ 600 galaxies at $z \sim 0.9$. Tiley et al. (2016) derived an evolution of the stellar-mass TFR zero-point of -0.41 ± 0.08 dex

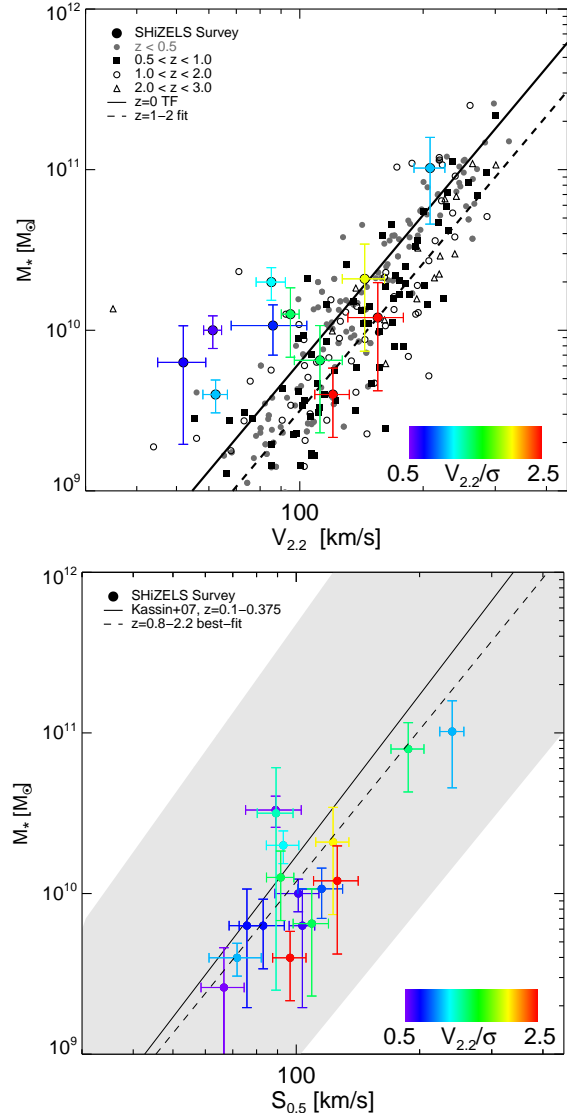

Figure 5. *Top:* Evolution of the stellar mass TF relation measured from the SHiZELS survey at $z = 0.8 - 2.23$ colour-coded using the $V_{2.2}/\sigma$ ratio. We only show our galaxies consistent with rotating systems together with their 1σ velocity and stellar mass uncertainties. The solid line denotes the TFR at $z = 0$ from Pizagno et al. (2005). The dashed line represent the best-fit TF relation at $z = 1 - 2$ from Swinbank et al. (2012a) based on the compilation of high-redshift points from Miller et al. (2011, 2012 $z = 0.6 - 1.3$); Swinbank et al. (2006 $z = 1$); Swinbank et al. (2012a $z = 1.5$); Jones et al. (2010b $z = 2$); Cresci et al. (2009 $z = 2$) and Gnerucci et al. (2011b $z = 3$). Galaxies with lower relative rotational support tend to be scattered to lower values along the velocity axis. This is consistent with the result found by Tiley et al. (2016). *Bottom:* The $M_*-S_{0.5}$ relationship measured from the SHiZELS survey at $z = 0.8 - 2.23$. The error bars show the 1σ stellar mass and $S_{0.5}$ mass uncertainties. The data is colour-coded as in the image above. The solid line represents the relation at $z \sim 0.2$ from Kassin et al. (2007) and the shaded area represents its 1σ uncertainty. The dashed line corresponds to the best-linear-fit to our data. Our scatter is tighter than the intrinsic $M_*-S_{0.5}$ scatter. The slope (0.32 ± 0.2) and the intercept at $10^{10} M_{\odot}$ (1.98 ± 0.09) found from our best-fit are consistent with the uncertainties of the $z \sim 0.2$ relation. This is consistent with no evolution of the $M_*-S_{0.5}$ relation with redshift up to $z = 2.23$.

10 *J. Molina et al.*

for rotationally supported galaxies defined with $V/\sigma > 3$. However, when they analysed their data without this V/σ constraint, they did not find any significant evolution of the M_* -TFR zero-point. We note that the M_* -TFR zero-point evolution found by [Tiley et al. \(2016\)](#) is contrary to some previous studies conducted at similar redshift ([Miller et al. 2011, 2012](#); [Di Teodoro et al. 2016](#)).

Similarly, [Weiner et al. \(2006a\)](#) and [Kassin et al. \(2007\)](#) introduced the kinematic measure $S_{0.5} = (0.5V^2 + \sigma^2)^{0.5}$ which considers support by both rotational motions and dispersion arising from disordered motions ([Weiner et al. 2006a](#)). [Kassin et al. \(2007\)](#) computed the M_* -TFR and M_* - $S_{0.5}$ relations within 544 galaxies at $0.1 < z < 1.2$. The M_* - $S_{0.5}$ relationship was found to be a tighter relation compared with the M_* -TFR relation, and this relation also showed no evolution with redshift in either intercept or slope.

When measuring circular velocities, to be consistent with the previous [Swinbank et al. \(2012a\)](#) campaign, we use velocities observed at 2.2 times the disk scale length ($V_{2.2}$) corrected for inclination effects. The disk scale length (r_d) is defined as the radius at which the galaxy $H\alpha$ intensity has decreased to e^{-1} (~ 0.37) times its central value.

3.1.1 The Stellar Mass Tully-Fisher Relation

In Fig. 5 we study the M_* -TFR at $z = 0.8 - 2.23$ using SHiZELS survey galaxies classified as disk by our kinematics analysis. The stellar masses and velocities of the comparison samples have been estimated in a fully consistent way, and these values (or corrections, where necessary) are presented in [Swinbank et al. \(2012a\)](#). We also show the TF relations at $z = 0$ ([Pizagno et al. 2005](#)) and the best-fit relation at $z = 1 - 2$ ([Swinbank et al. 2012a](#)) from the literature. Even though we do not attempt to fit a relation to our data, we can see from Fig. 5 that apparently our sample is consistent with no evolution in the zero-point of the M_* -TFR out to $z = 0.8 - 2.23$.

As suggested by [Tiley et al. \(2016\)](#) we estimated the rotational velocity to dispersion velocity ratio. This is done by calculating the $V_{2.2}/\sigma$ ratio. We show this parameter colour-coded in Fig. 5. We find that galaxies with lower $V_{2.2}/\sigma$ ratio (i.e. with greater pressure support) tend to be scattered to lower values along the rotational velocity axis: this is consistent with [Tiley et al. \(2016\)](#), who found an evolution of the zero-point TFR at $z = 0.9$ when they select galaxies with $V_{80}/\sigma \geq 3$ within their sample (V_{80} is the velocity observed at the radius which encloses the 80% of the total $H\alpha$ intensity of the galaxy), although the complete sample is consistent with no evolution in the TFR zero-point.

This result suggests that the large scatter measured from the M_* -TFR at high- z may be produced by galaxies which are supported by a combination of rotational and disordered motions. If we do not take into account this effect then this could produce misleading conclusions. We note that galaxies which have greater rotational support within the SHiZELS survey tend to lie closer to the M_* -TFR at $z = 2$ derived by [Swinbank et al. \(2012a\)](#), whilst galaxies with strong disordered motion support tend to be have a greater offset from this relationship. This trend perhaps implies that galaxies may be moving onto the M_* -TFR with time as the dynamics of the stars and gas in the central few kpc of the halos are yet to relax into a disk-like system.

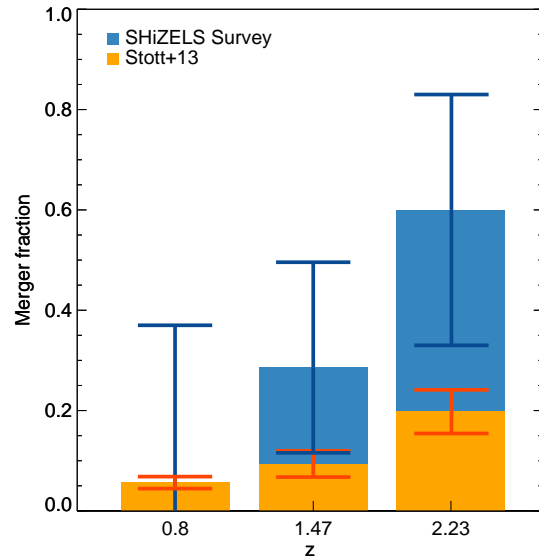

Figure 6. In blue are represented the kinematically selected mayor merger fractions measured from the SHiZELS survey at $z = 0.8 - 2.23$. The error bars for the SHiZELS survey are estimated by assuming binomial statistics (see §3). The orange colour correspond to the data at similar sSFR ($\sim 10^{-9} \text{ yr}^{-1}$) from [Stott et al. \(2013a\)](#), who use the M_{20} morphological criterion to classify mergers. We find higher merger fraction at each redshift slice.

3.1.2 The M_* - $S_{0.5}$ Relation

The stellar mass TFR is found to be sensitive to which process dominates the support of the galaxy. The scatter increases when galaxies with pressure support equivalent to the rotational support ($V/\sigma \sim 1$) are included. Perhaps a more fundamental relation is the M_* - $S_{0.5}$ relationship ([Weiner et al. 2006a](#); [Kassin et al. 2007](#)) which consider the support given by ordered and disordered motions within the galaxy. In Fig. 5 we show the M_* - $S_{0.5}$ relation for the SHiZELS survey using the inclination-corrected speeds, colour-coded by V/σ ratio. We also show the $z \sim 0.2$ M_* - $S_{0.5}$ relationship from [Kassin et al. \(2007\)](#) and the best linear fit to the SHiZELS survey sample. We note that this relationship is fitted in the form $\log_{10}(S_{0.5}) = a + b \log_{10}(M_* \times 10^{-10} M_\odot)$, where ‘a’ is the intercept. From Fig. 5 it can be seen that our sample agrees with the $z \sim 0.2$ M_* - $S_{0.5}$ relationship within 1σ uncertainty: this is consistent with either no evolution of intercept or slope of the M_* - $S_{0.5}$ relation with redshift ([Kassin et al. 2007](#)). Despite the low number statistics, we do not identify any dependency on V/σ for this relation, contrasting with what was previously seen in the M_* -TFR (Fig. 5).

This relationship is consistent with a scenario of galaxy formation that begins with matter assembling into a dark-matter halo with turbulent kinematics. The baryonic component forms protodisks that are initially supported by a combination of rotational and disordered motions. Finally, the material in these protodisks settles down, unless they undergo major mergers ([Kassin et al. 2007](#)).

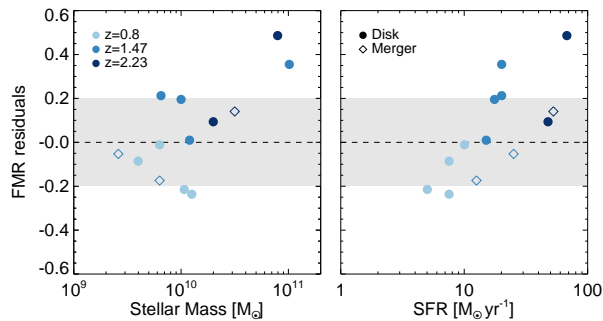

Figure 7. The metallicity residuals within the SHiZELS Survey calculated as the subtraction between the measured metallicities and the metallicities predicted by the FMR of Stott et al. (2013b). We plot against the stellar mass (*left*) and SFR (*right*). Negative values mean metallicities lower than expected by the FMR. The sky blue, blue and dark blue colours represent the sources at $z = 0.8, 1.47$ and 2.23 respectively. Diamonds and circles show targets classified as Merger and Disks respectively from kinemetry criterion (see §3). The shaded area corresponds to the scatter of the FMR of 0.2 dex (Stott et al. 2013b). The measured residuals expected from the FMR is 0.23 dex, which is consistent with the relationship. We find no trend between galaxy morphology and metallicity content within our sample.

3.2 Merger Fraction

To test whether it is galaxy mergers, secular processes or a combination of both that dominate and drive galaxy evolution at the peak era for star formation, we need to measure the merger fraction (f_{merg}) at this epoch. From a theoretical perspective in the Λ CDM paradigm, dark matter haloes merge hierarchically from the bottom up (e.g. Lacey & Cole 1993; Cole et al. 2000; Springel et al. 2005). As baryonic matter traces the underlying dark matter, we expect that galaxies merge hierarchically as well.

Stott et al. (2013a) noted that the typical sSFR for galaxies increases with redshift within the HiZELS sample. They found greater merger fractions with increasing sSFR suggesting that major mergers can lead to galaxies having unusually high sSFR. Although the targets within the SHiZELS survey have higher SFR at higher redshift, they also have higher stellar masses, maintaining the median sSFR per redshift slice roughly constant (see Fig. 1).

We define ‘merger fraction’ as the number of galaxies classified as merger by the kinemetry criterion (see §3) divided by the total number of galaxies in the redshift slice (we do not consider the unresolved galaxy classified as ‘compact’ in this analysis).

In Fig. 6 we show the variation of the merger fraction as a function redshift for the $z = 0.8, 1.47$ and 2.23 redshift slices. From the SHiZELS survey we find a merger fraction of $0.0^{+0.4}$, $0.3^{+0.2}_{-0.2}$ and $0.6^{+0.2}_{-0.3}$ at $z = 0.8, 1.47$ and 2.23 , respectively. The error in the merger fraction were estimated by assuming binomial statistics. These values are consistent with previous IFU surveys (e.g. Shapiro et al. 2008; Förster Schreiber et al. 2009).

We compare with Stott et al. (2013a) who used the M_{20} morphological classification (Lotz et al. 2004) in the HiZELS sample but we only consider the merger fraction calculated

for those galaxies with similar sSFR values ($\sim 10^{-9} \text{ yr}^{-1}$). From Fig. 6 we find a clear increase in merger fraction from $z = 0.8$ to $z = 2.23$ that seems to be stronger than the increase found by Stott et al. (2013a). This suggests that methods based on surface brightness morphology classification may underestimate the number of major mergers at low sSFR and similar ($0''.2 - 0''.7$) spatial resolution. We conclude that galaxy mergers may have a dominant role in the evolution of ‘typical’ star-forming galaxies at $z \geq 1.5$, but we caution regarding the low number of statistics.

3.3 Metallicity Content

Measuring the internal enrichment and radial abundance gradients of high redshift star-forming galaxies provides a tool for studying the gas accretion and mass assembly process such as the gas exchange with the intergalactic medium. The $[\text{N II}]/\text{H}\alpha$ emission line ratio can be used to determine the metallicity of high- z galaxies using the conversion $12 + \log_{10}(\text{O}/\text{H}) = 8.9 + 0.57 \log_{10}([\text{N II}]/\text{H}\alpha)$ (Pettini & Pagel 2004). Our sample has a median metallicity of $12 + \log_{10}(\text{O}/\text{H}) = 8.57 \pm 0.05$, which is slightly below but still consistent with the solar value. Also our galaxies have metallicities consistent with previous studies that derive typical metallicities of 8.66 ± 0.05 and 8.58 ± 0.07 for $\text{H}\alpha$ -selected samples at $z \sim 0.81$ and $z \sim 0.84 - 2.23$ respectively (Queyrel et al. 2012; Swinbank et al. 2012a; Sobral et al. 2013a).

A relationship between mass, metallicity and SFR has been found in both the local and high- z Universe (Mannucci et al. 2010; Lara-López et al. 2010, 2013) and measured by Stott et al. (2013b) for a sample drawn from the HiZELS survey at $z \sim 1$. The shape of this ‘Fundamental Metallicity Relationship’ (FMR) is, to first order, a manifestation of the positive correlation of the metallicity and stellar mass at fixed SFR and a negative correlation of the metallicity and SFR at fixed stellar mass. The shape of the FMR can be explained as the result of the competing effects of chemical enrichment of the gas by the evolving stellar population, star-formation driven winds and the inflow of gas from the IGM. We test this relationship and its dependence on galaxy morphology using the SHiZELS Survey. In Fig. 7 we show the difference between the measured metallicity of the SHiZELS Survey and the metallicity predicted by the FMR at $z = 0.84 - 1.47$ (Stott et al. 2013b). The measured scatter is consistent within 1σ uncertainties from the FMR. On average, we find that the metallicity content in our star-forming galaxies is similar to galaxies of similar mass and SFR at $z \sim 0.1$ (Stott et al. 2013b). We note that this suggests no evolution in the FMR up to $z \sim 2.23$. Although most of our galaxies at $z \sim 2.23$ are classified as mergers, we find no trend between mergers and disks morphologies within the residuals from this relationship.

In order to derive the chemical abundance gradients in our sample, we use the disk inclination and position angle (derived from the best-fit dynamical model) to define ~ 1 kpc annuli centred at the dynamical centre. Within each annulus we stack the spectrum (considering emission line offsets in each annulus) to measure the average $[\text{N II}]/\text{H}\alpha$ flux ratio by fitting a double gaussian profile with coupled gaussian widths. For a detection we enforce $\text{S/N} > 5$ thresholds at each radius and a minimum of three radial detections per target. Then we fit a straight line as a function of galaxy ra-

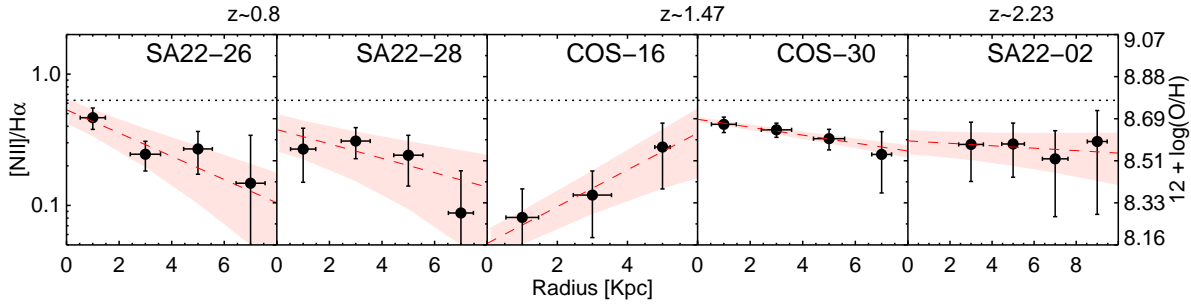

12 *J. Molina et al.*

Figure 8. Metallicity gradients for five galaxies in our observed sample (Table 1) from spatially resolved measurements as function of the physical radius derived from the best kinematical model. The red dashed line represents the best linear fit and the shaded region represents 1-dex uncertainties. The dotted line shows the AGN limit of $\log_{10}([\text{N II}]/\text{H}\alpha) \approx -0.2$ at $z = 0.8$ (Kewley et al. 2013). This suggests the potential for a starting AGN activity within the central kpc in source SA22-26. Within our sample, SA22-02 has a gradient consistent with zero, SA22-26, SA22-28 and COS-30 have negative gradients and COS-16 source has positive metallicity gradient.

dius in each case. From the eight galaxies with measured $[\text{N II}]/\text{H}\alpha$ flux ratio detected from their one-dimensional spectra (see § 2.6), five galaxies present reliable $[\text{N II}]/\text{H}\alpha$ gradients. We show this in Fig. 8 and the individual metallicity gradient values are reported in Table 1. We find a median of $\Delta \log_{10}(\text{O}/\text{H})/\Delta R = -0.014 \pm 0.009 \text{ dex kpc}^{-1}$, i.e. a median gradient consistent with a negative gradient. In comparison, Swinbank et al. (2012a) found a slightly steeper median metallicity gradient ($\Delta \log_{10}(\text{O}/\text{H})/\Delta R = -0.027 \pm 0.006 \text{ dex kpc}^{-1}$) from their sample at similar redshift range. Considering the combination of both studies (the full SHiZELS sample), we find a median metallicity gradient of $\Delta \log_{10}(\text{O}/\text{H})/\Delta R = -0.026 \pm 0.008 \text{ dex kpc}^{-1}$. This result suggests that either low metallicity gas from the halo or IGM is accreted onto the outer disk, or metal enrichment is higher in the central region of the galaxy.

We do not have simultaneous access to $[\text{O III}]5007$, $\text{H}\beta$, $\text{H}\alpha$, and $[\text{N II}]6583$ or $[\text{S II}]6717, 6731$ emission lines to distinguish any possible strong AGN contribution within our sample via a BPT diagram (Baldwin, Phillips & Terlevich 1981). Considering $\log_{10}([\text{N II}]/\text{H}\alpha) \approx -0.2$ flux ratio as a rough limit for identifying an AGN at $z \geq 0.8$ (Kewley et al. 2013), only the central kpc of SA22-26 might be affected by low AGN contamination. This conclusion is also supported by the lack of broad recombination lines in the spectra.

Just one galaxy (COS-16) shows a positive metallicity gradient within the SHiZELS survey – a system which is also classified as a major merger by the kinemetry criterion. From cosmological simulations, Tissera et al. (2016) found that galaxies with positive metallicity gradients tend to exhibit morphological perturbations and close neighbours. They suggest that those galaxies have a high probability of interactions/mergers due to a high number of surrounding satellites. They analyse the evolution of a gas-rich equal-mass merger and they found that both negative and positive metallicity gradients might be produced during different stages of the merger evolution.

We note that we do not find any clear correlation between the asymmetries measured from the kinemetry coefficients (K_V , K_σ and K_{Tot}) and the metallicity gradients observed within the SHiZELS survey.

3.4 Spatially Resolved Chemical Abundances

A tentative anti-correlation between the metallicity gradient and the global integrated metallicity was previously hinted at the ‘Mass Assembly Survey with SINFONI in VVDS’ (MASSIV), using star-forming galaxies at $z \sim 1.2$ (Queyrel et al. 2012). They suggest that metallicity gradients are more frequently negative in metal-rich galaxies and more frequently positive in low-metallicity galaxies. In Fig. 9 we show the anti-correlation suggested by Queyrel et al. (2012), adding our SHiZELS galaxies and the sample observed by Stott et al. (2014). We calculate the average and median values per $\Delta \log_{10} = 0.1$ bin. Then we calculate the best linear fit to the average and median values. The slope is 2.5σ from being flat (2.0σ by fitting the median values), but due to beam smearing effects and inclination angles the measured metallicity gradients are likely to be underestimated, especially those of Stott et al. (2014) and MASSIV samples which were measured on seeing-limited conditions ($\sim 0''.7$). Stott et al. (2014) estimated that their observed metallicity gradients reflects only $\sim 70\%$ of the true values. This suggests that if we alleviate inclination angle effects with higher resolution IFU observations, these results will not change. Our results support the previous suggestion by Queyrel et al. (2012).

We note that positive metallicity gradients could be explained by the infall of metal-poor gas from the IGM into the centre of the galaxy, diluting the gas and lowering its metallicity in the central regions. If the funnelling of metal-poor gas into the centres of galaxies is triggered by galaxy mergers, then from the merger fraction estimated for the SHiZELS Survey (Fig. 6), we should expect to find more systems with positive/flat metallicity gradients at $z \sim 2$.

Taking into account the metallicity gradients measured from the SHiZELS Survey (Fig. 9), we compare its evolution with redshift with the prediction from the ‘Galaxies-Intergalactic Medium Interaction Calculation’ simulation (GIMIC; Crain et al. 2009; McCarthy et al. 2012; Swinbank et al. 2012a), where the metallicity gradient evolution within disk galaxies is a consequence of a decrement of gas inflow rates from $z = 2$ to $z = 0$ and redistribution of gas within the galaxy disk. The observed metallicity gradients for disk galaxies within the SHiZELS survey do not support the trend predicted by the GIMIC simulation between $z = 0 - 2$. Nevertheless, we note that a

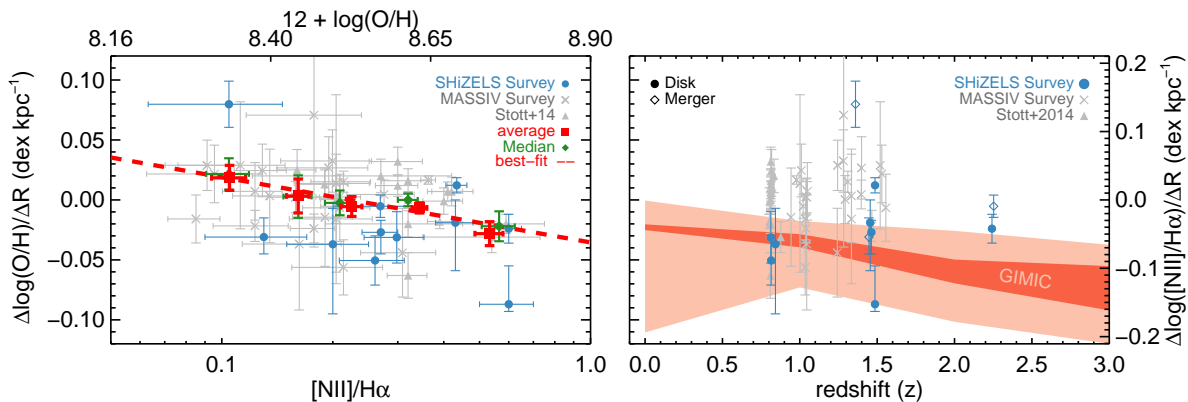

Figure 9. *Left:* Metallicity gradient as a function of the $[N II]/H\alpha$ emission line ratio from the one-dimensional spectra of each galaxy. The sky blue circles are individual galaxies within the SHiZELS Survey. The grey crosses denotes the sample from the MASSIV Survey (Queyrel et al. 2012) corrected for a Pettini & Pagel (2004) metallicity calibration. The grey triangles denotes the sample from Stott et al. (2014). The red squares and green diamonds show the average and median metallicity content and metallicity gradient per $\Delta \log_{10}(O/H)=0.1$ bin respectively. The error bars shows 1σ uncertainties. Within the literature, we only consider $[N II]/H\alpha$ fluxes ratio above 1σ detection threshold. The red-dashed line shows the best linear fit ($\Delta \log_{10}(O/H)/\Delta R = a + b \times \log_{10}(O/H)$) to the average values with a slope value of $a = -0.10 \pm 0.04$ and zero-point of $b = 0.89 \pm 0.30$. The SHiZELS survey supports the anti-correlation such that metallicity gradients tend to be negative in metal-rich galaxies and positive in low-metallicity galaxies (see also Queyrel et al. 2012). *Right:* Metallicity gradient as a function of redshift. We also show the theoretical evolution of the metallicity gradient with redshift from the GIMIC simulation (Crain et al. 2009; McCarthy et al. 2012). The shaded-red area shows the range of metallicity gradients for all disk galaxies in the simulation in the mass range $9.5 < \log_{10}(M/M_{\odot}) < 11.5$, whilst the shaded light-red denotes the 1σ scatter at each epoch. Diamonds and circles show targets classified as Merger and Disk respectively from kinemetry criterion (see §3). The metallicity gradients measured from the SHiZELS survey do not support the evolution predicted from the GIMIC simulation from $z = 0$ to $z = 1.47$.

much larger sample of disk galaxies at $z = 2$ are needed to further test this.

4 CONCLUSIONS

We present new AO-aided SINFONI IFU observations of spatially resolved $H\alpha$ kinematics of eleven mass-selected ($M_{*} = 10^{9.5-10.5} M_{\odot}$) ‘typical’ star-forming galaxies from the wide-field narrow-band HiZELS survey in three redshift slices, $z = 0.8, 1.47$ and 2.23 . All galaxies lie within $< 30''$ of bright ($R < 15.0$) stars enabling natural guide star AO assisted observations. Modelling the $H\alpha$ dynamics along the major kinematic axis of our galaxies, we derive a median dynamical-to-dispersion support of $V_{\max} \sin(i)/\sigma = 1.6 \pm 0.3$ (with a range of 1.1–3.8). We classify the galaxies using a kinemetry analysis (Shapiro et al. 2008) finding six disk-like galaxies and four mergers. One galaxy is unresolved. These new observations are combined with a previous similar study (nine galaxies taken from Swinbank et al. 2012a) to create a homogeneously selected sample of star-forming galaxies with dynamical characterisation at $\sim kpc$ scales near the peak of the cosmic star-formation rate density.

We find a tentative increase of the merger fraction as a function of redshift ($f_{\text{merg}} \sim 0.0^{+0.4}, 0.3^{+0.2}_{-0.2}$ and $0.6^{+0.2}_{-0.3}$ at $z = 0.8, 1.47, 2.23$, respectively). Nevertheless, our results are consistent with previous IFU surveys (Shapiro et al. 2008; Förster Schreiber et al. 2009), although we find higher merger fractions at a given sSFR in comparison to previous analyses by Stott et al. (2013a) who used a morphological classification from *HST* near-IR imaging.

We combine our observations with previous studies of

intermediate and high-redshift galaxies (Swinbank et al. 2006; Cresci et al. 2009; Jones et al. 2010b; Gnerucci et al. 2011b; Miller et al. 2011, 2012; Swinbank et al. 2012a) to investigate the stellar mass Tully-Fisher relation. We find that the scatter of this relation is affected by the galaxy pressure support (V/σ) – a result which is consistent with Tiley et al. (2016). On the other hand, we also investigate the M_{*} - $S_{0.5}$ (Kassin et al. 2007) relation within the SHiZELS survey at $z = 0.8 - 2.23$. The kinematic measure $S_{0.5} = (0.5V^2 + \sigma^2)^{0.5}$ consider support by both rotational motions and dispersion arising from disordered motions (Weiner et al. 2006a). Our results are consistent (within 1σ) with the M_{*} - $S_{0.5}$ relationship found at $z \sim 0.2$, suggesting little or no evolution of this relation as function of redshift.

We measured the residuals from the ‘Fundamental metallicity relation’ (Stott et al. 2013b) at $z = 0.84 - 1.47$, finding that the scatter is consistent with measurements errors, suggesting no variation in the FMR up to $z = 2.23$.

We measure metallicity gradients ($\Delta \log_{10}(O/H)/\Delta R$) using the $[N II]/H\alpha$ ratio for 3, 7 and 2 galaxies at $z = 0.8, 1.47$ and 2.23 within the SHiZELS Survey. These metallicity gradients ranges between -0.087 and 0.08 dex kpc^{-1} , with a median metallicity gradient of $\Delta \log_{10}(O/H)/\Delta R = -0.027 \pm 0.008$ dex kpc^{-1} . The evolution of metallicity gradients as a function of redshift in our modest sample at $z \leq 2$ do not exhibit any clear redshift trend such as the predicted by the GIMIC simulation for galaxy disks, where gas inflow rate decreases with decreasing redshift progressively. However, larger samples at $z = 2$ are needed to further test this.

We show that the metallicity gradient and global metallicity content are consistent with the anti-correlation suggested by Queyrel et al. (2012). This can be explained by

the scenario in which infall of metal-poor gas from the IGM into the central part of the galaxy drives the positive gradients.

ACKNOWLEDGMENTS

APPENDIX A: SERENDIPITOUS DETECTION

Within the SA22-26 data-cube we found an unexpected emission line at $\lambda \sim 1.203 \mu\text{m}$. This emission line does not coincide with any expected emission line emitted from the SA22-26 source as it corresponds to $\lambda_{\text{rest}} \sim 0.663 \mu\text{m}$ in this galaxy’s restframe. This unexpected emission line overlaps spatially with part of the $\text{H}\alpha$ emission from SA22-26 source (Fig. A1-top). Furthermore, the kinematical behavior of this emission line region shows a position angle (Fig. A1-bottom) which differs from the position angle derived for the SA22-26 source (Fig. 3). This suggest that this serendipitous emission does not comes from SA22-26. We did not find any other emission lines associated with this galaxy which could be used for determining the redshift of this possible new source. We call this source as SA22-26B. If we assume that this emission line is also a redshifted $\text{H}\alpha$ emission line, then SA22-26B is offset redwards by $\sim 5500 \text{ km s}^{-1}$ (in the line-of-sight direction, $z \sim 0.833$) from the SA22-26 source. The modest redshift difference if the emission line is $\text{H}\alpha$ would be consistent with no lensing. We note that the emission from SA22-26 shows no sign of extinction by SA22-26B supporting the fact that this galaxy is background.

This paper has been typeset from a $\text{T}_{\text{E}}\text{X}/\text{L}^{\text{A}}\text{T}_{\text{E}}\text{X}$ file prepared by the author.

Figure A1. *Top Left:* Intensity contours of our serendipitous detection (red) and SA22-26 (green-dashed) sources within the SINFONI data-cube. The dashed line shows the position angle derived for SA22-26 source. There is a clear spatially overlap between both emissions. *Top Right:* Spatially integrated one-dimensional spectra of SA22-26B. The emission is integrated within the red contour showed in top-left figure. The red-dashed line shows the emission line detected at $\lambda \sim 1.203 \mu\text{m}$. The green-dashed lines show the $\text{H}\alpha$, $[\text{N II}]\lambda\lambda 6583, 6548$ emission lines for the SA22-26 source extracted from the same area. *Bottom:* Intensity, velocity, line-of-sight velocity dispersion (σ), residual field, one-dimensional velocity dispersion profile and one-dimensional velocity profile (as in Fig. 3) for our serendipitous detection. The spatial scale is showed in arcseconds due to the uncertain redshift determination.
